Source: Reset from EPA 1977b.

Please note that the individual doses are in *millirem per year*, while the population dose is in *person-rem per year*, not an integrated dose as seen in examples quoted earlier. They did not use the environmental dose commitment concept since it could apply to only a portion of the data.

This summary has not been updated. The fact that such a review was done by EPA is salutary, but it is hoped that the effort will be continued with periodic updates, especially to add the contributions from radon in homes (discussed elsewhere).

We have already mentioned that the periodic UNSCEAR reports gave population dose estimates for each radionuclide they considered. The most complete reviews were in the 1972 and 1977 reports. They are divided between doses from fallout and those from other sources, and they include comments on the pathways used in the calculations. The doses are given as *individual* doses, i.e., *per caput* doses to members of the population in northern or southern temperate zones or the world population. We have shown illustrations of the results in an earlier chapter.

As we approach the end of the very active decade of the seventies and move into the 1980s, we find the scene shifting back to fallout and away from nuclear power. This is largely because of the retrospective evaluations generated by the litigations described in chapter 12.

The work of the NAEG (chapter 14) and the enormous compilation of information at the Las Vegas information center concerning fallout from NTS (chapter 12) are, of course, primarily aimed at dose assessment; this time retrospective rather than prospective. There was (and is) a formal "Dose Assessment Advisory Committee," whose work was reviewed in chapter 12.

A recent NCRP annual meeting (1983) included updates of some of these evaluations, e.g., Anspaugh and Church (1983) on NTS; Robison (1983) on the Marshall Islands; also discussions of radon in homes (Rundo and Toohey (1983); various manmade sources released into the environment (Jacobs 1983); and general environmental radioactivity (Harley 1983). There was also a review of the assessment work done and projected for Three Mile Island (Daniels 1983); a general update on doses for the nuclear fuel cycle (Kahn 1983); and a review of the uncertainties of the environmental radiological assessment models (Hoffman and Miller 1983). There was, finally, a masterful review by Dunster reassessing the radiological impact of the Windscale Reactor accident (Dunster 1983). All of these depend, to a greater or lesser degree, on the models and transfer function structure we have described in this chapter. The most extensive overt use of environmental modeling and transfer factors occurs in the paper by Robison on the radiological dose assessments of the northern Marshall Islands. The time periods he took for dose integration were thirty years and fifty years. In other words, the focus was on the generation now inhabiting the atolls rather than on all of humanity over all of time. The thirty-year whole-body dose equivalents varied greatly with the atolls and islands.^(a) The maximum occurred on the northern islands of Rongelap (2.1 to 11 rem from all exposure pathways). The minimum was 0.072 to 0.13 rem on the islands of Likiep. The Lawrence Livermore people also produced figures for the maximum annual whole-body dose equivalent rates for uninhabited islands.

The doses and dose-rates were, in general, from 1% to 5% of the federal guideline of 500 mrem/yr above background. The highest estimated dose equivalent for an inhabited atoll was 10% to 50% of the guideline.

(a) The Brookhaven diet gave, in general, higher dose-equivalent rates than the diet developed by the Micronesian Legal Services Corporation, which Lawrence Livermore used.

Many more examples could be cited, but we have seen enough to discern the trend and the mechanisms.^(a) Population dose assessment has been couched officially by ICRP in terms of integration to infinity. Most current assessments seem content to use thirty to fifty years, sometimes one hundred years, or even annual dose rates. There are many problems with the extremely long extrapolations. Mathematically they are easy, but practically, doubts arise about the validity of input figures for the environmental pathways. A lot of geological changes can occur, watersheds disappear and appear, oceans change levels, climates change, etc., over a few million years. For many ordinary problems, there seems to be a tendency to stay with a scenario that can be visualized with a modicum of assurance. Thus, for the present we may be, consciously or unconsciously, enfolded the philosopher's statement: "The study of infinity will require eternity."

B. Resuspension

1. The Problem

We have reserved discussion of this special aspect of atmospheric transfer to put it in juxtaposition to consideration of surface and soil contamination standards. It is an area where the biomedical establishment and physical scientists have worked together, but it is more aerosol physics than biology.

The basic phenomena of resuspension concern the pick-up by wind of particles that have been deposited on the earth's surface. They are a part of the general phenomena of wind erosion that have been broadly investigated since the 1930s. However, special attention was drawn to the possibilities for and significance of resuspension by the deposition of fallout in arid environments, and in recent years the redistribution of long-lived insoluble radionuclides, such as plutonium and the actinides, at weapons testing sites and around high-level radioactive waste disposal areas. We saw some of the practical problems of health implications in connection with the special safety shots described in chapter 14.

Resuspension is not a single process. At small particle sizes ($<50 \mu\text{m}$) it is largely airborne transport; between 50 and $1,000 \mu\text{m}$, it is largely saltation—a leaping or hopping of one particle over another; above $1,000 \mu\text{m}$, it is largely surface creep of the particles.^(b) Obviously, particles larger than about $10 \mu\text{m}$ are of little biomedical concern as inhalation hazards, but they may deposit on vegetation and thus enter a food pathway. The latter is of more importance with the soluble fission products than with the insoluble actinides. Let it be clear that

(a) *Note added in proof:* In 1984, the EPA provided an update of the data shown in table 15.10 and an expansion to individual facilities (EPA 520/1-84-022-1, vols. 1 and 2). The agency also prepared a comprehensive review of occupational exposures in the United States in the year 1980 with a summary of trends for 1960–1985 (EPA 520/1-84-005). These provide new information for dose assessment, particularly in the environs of nuclear facilities, but no disconcerting surprises.

(b) Intuitively, it might be expected that the smaller particle sizes would contribute the most. Field tests indicate a surprisingly large contribution of particle sizes in the range of the saltation mechanism. Evidently, the "hops" can go fairly high, and the particles can be carried off by wind. Also, the larger particles can contribute by dislodging others. The literature on wind erosion shows many instances where saltation predominates quantitatively (Chepil 1945).

resuspended particles can travel long distances from their point of origin, and inhalation of the transported dust has been considered a significant potential hazard.

Interest in doing research on resuspension phenomena with radionuclides seems to have begun at Hanford, but it spread rather quickly to the laboratories involved with the NTS activities. This was in the early 1950s. John W. Healy, a biophysicist at Hanford, can be considered along with some Hanford colleagues (James Fuquay, G. R. Hilst) as having started the ball rolling. A good place to begin is with the review paper by Healy and Fuquay (1958) given at the second Atoms for Peace Conference in Geneva. Here the relationships of wind transport to the general problems of soil erosion are depicted, and the problems of mathematical treatment of the phenomena are made evident. An entity is introduced that relates to the deposition velocity conventions already discussed in connection with the Idaho Falls field work on iodine (CERT tests). It considered the rate of fallout and was termed the "coefficient of deposition." It was defined as:

$$\Lambda = \frac{\text{rate of deposition per unit area of ground per second}}{\text{volumetric concentration per unit volume of air}}$$

Healy and Fuquay also defined a surface pick-up coefficient, K , that was not too different from the resuspension factor we will define presently. It could be evaluated by measurements downwind from sources of particles. They describe two experiments carried out at Hanford in 1954–1955 (Hilst 1955) done to enable order-of-magnitude estimates of this coefficient, using a fluorescent powder with a mass-median diameter of about $7 \mu\text{m}$. The first experiment was designed to measure changes in airborne concentrations over several days. The second experiment studied differences in pick-up rates among different surfaces. In both experiments, the values of K fell between 1×10^{-7} and 9×10^{-8} , the lower figure appearing, as might be expected, from a wet surface.^(a) The Hanford group then used these data and assumptions regarding particle diameter and wind speed to calculate particle concentration and, when combined with information on the biological effects of radioactive particles, an estimate of potential hazard.^(b)

Healy has kept a lively interest in the phenomena of resuspension ever since (e.g., Healy 1976a,b; 1980) and has been a consistent and impressive contributor to the field. This persisted long after his move from Hanford to Los Alamos. (Many of Healy's later contributions were tied to standards for soil, which we will review in the next section.) The Los Alamos group soon joined in (e.g., Langham 1969), and, at Hanford, Kathren (1968) presented a model that we will consider in a later connection.

Those concerned with NTS were aboard also, and the Lawrence Livermore Laboratory, particularly Lynn Anspaugh, began regular contributions, many of which tied in to the work of the NAEC. Practical aspects became part of the work around the Rocky Flats plant (chapter 11), and there were comparisons

(a) These values were at 50 cm above the ground.

(b) This was for an undisturbed area contaminated by radioactive materials. As we saw in chapter 14, much interest was attached also to the effects of human activities, such as vehicular traffic, on resuspension factors.

between the arid environments of the west and the humid environments of the east and southeast.

2. The Resuspension Factor

In the late 1950s and through the 1960s, a strong urge was felt to devise some simple expression for resuspension and, it was hoped, develop a preferred value or a narrow range of values for such an expression that could be used for hazard estimation. Many practical operations depended on such estimates. As a result, a factor somewhat like that described by Healy, but omitting the parameter of time, came into frequent use. It was termed "The Resuspension Factor," R , and was defined as:

$$R = \frac{\text{air concentration in activity or mass units per m}^3}{\text{surface concentration in activity or mass units per m}^2}$$

The units were, of course, m^{-1} .^(a)

The resuspension factor was applied to industrial and commercial environments, e.g., particles resuspended from floors or benches by indoor air agitation or human activities, as well as to the outdoor environment. As might be expected in a situation where the pickup could be markedly influenced by changes in wind speed, the nature of the surface of deposition, and many other factors in the ambient environment,^(b) the range for this factor was found to be enormous, especially in desert environments. Mishima (1964), at Hanford, could find values all the way from 10^{-13} to 10^{-3} m^{-1} . These are obviously extremes.^(c)

As Healy pointed out in a relatively recent review (Healy 1980), the most frequent values for mechanical disturbance were in the range of 2×10^{-6} to $7 \times 10^{-5} \text{ m}^{-1}$ and from 10^{-8} to $2 \times 10^{-6} \text{ m}^{-1}$ for freshly deposited material left undisturbed.

K. Stewart (1964) did some experimental work that led him to conclude that an appropriate average value of the resuspension factor for use in hazard evaluation for both field and laboratory was 10^{-6} (10^{-5} under conditions of moderate activity). This factor was used for developing general guidelines (Brodsky 1980 and work cited therein), although about all that can be said for it is that few figures in normal operations will be much higher, and it is, therefore, conservative. Many, many measurements were made in the environment, particularly at NTS, to evaluate "the" resuspension factor. They sometimes measured factors higher than $10^{-6}/\text{m}$, and Kathren suggested a very conservative value of $10^{-4}/\text{m}$.

If one contemplates what we discussed earlier concerning changes in the availability of surface-deposited radionuclides with time, it should be apparent

(a) Sometimes the original units were cm^3 and cm^2 and the final answer was cm^{-1} . If readers find puzzling inconsistencies in their reading of the literature, they should check the units used by the authors.

(b) As discussed in volume 2 of the Whicker and Schultz book (1982), these include velocity; turbulence; density, which, is in turn a function of temperature, pressure, and humidity; and viscosity among the atmospheric variables; and texture, particle size distribution; cohesiveness, moisture content, topography, surface roughness, and plant cover among the surface variables.

(c) The range for indoor environments was usually much less, and the values tended to be 10^{-6} m^{-1} or lower.

that any given resuspension factor is most unlikely to be constant for any length of time under field conditions. It will be remembered from chapter 14, for example, that Wilson, Thomas, and Stannard (1960) reported an apparent half-life of thirty-five days for the air concentrations of plutonium after the Test Group 57 safety shot at NTS. Langham (1969) used this value in assessing future hazards for plutonium contamination. Kathren (1968) used forty-five days. Any such figures are undoubtedly of only temporary validity. Indeed, like the resuspension factor itself, there is little reason to expect a constant value for the half-life. If values on the order of thirty-five to forty-five days actually persisted, the projected resuspension factors after ten years would be very much lower than are actually found, e.g., 10^{-29} and 10^{-36} m^{-1} for forty-five and thirty-five days half-life, respectively. The lowest value found in practice was developed in work at the GMX site at NTS, where over twenty plutonium safety shots had taken place. The Lawrence Livermore people used Anderson high-volume cascade impactors to resurvey the area in the summer of 1972, about seventeen years after deposition. They found a mean value for the resuspension factor of $3 \times 10^{-10}/\text{m}$. Additional measurements made by Reynolds Electric and Engineering Company gave $2 \times 10^{-9}/\text{m}$. These are a far cry from 10^{-29} to 10^{-36} !

Anspaugh et al. (1973), from Lawrence Livermore, examined the behavior of deposits from the cratering event "Schooner" and the accidental venting associated with the "Baneberry" event. They set up fairly elaborate sampling stations and followed the airborne radioactivity for six weeks after the Schooner event and for up to ten months after Baneberry. They came back after two years for a FIDLER survey (see chapter 14) of surface deposition. As much as half of the deposited debris was moved by the saltation process within twenty-four hours. The variation of air activity with time, after the Schooner shot, based on the activity of ^{181}W gave a half-life of thirty-eight days, quite similar to the figure for plutonium given by Wilson, Thomas, and Stannard. However, this covered only about 1,250 hr after the shot. For Baneberry, the half-life was seventy-six days based on data taken over a period of several months. There was considerable scatter of the points, however, as illustrated in figure 15.16A and B.

There were many other investigations of the trend of resuspension with time. In toto, these resulted in a formulation by Anspaugh, Shinn, and Wilson (1974) as follows:

$$K(t) = 10^{-4} \exp(-0.15 \text{ d}^{-1/2} \sqrt{t}) \text{ m}^{-1} + 10^{-9} \text{ m}^{-1}$$

where $K(t)$ is the resuspension factor in m^{-1} and t is the time since the contaminating event. The second term is introduced on the assumption that no further decrease occurs in the resuspension process after the level of 10^{-9} m^{-1} is reached.^(a)

There were other views on the change of the resuspension factor with time. Healy (1984) takes the view that the data have so much scatter that no reliable value for a half-life can be derived. Indeed, there may be very little change in the availability of material for resuspension once the initial settling out processes are over.

(a) The constraints that underlie the formula are:

1. half-time for decrease in first ten weeks should approximate five weeks
2. this should about double over the next thirty weeks
3. the initial resuspension factor was 10^{-4} m^{-1} .

FIGURE 15.16A.

Tungsten-181 air activity as a function of time at the five downwind stations within six miles that were closest to the line of maximum deposition from Project Schooner. Data were normalized to the first sample taken after seventy hours had elapsed following the detonation. (Redrawn from Anspaugh et al. 1973.)

**FIGURE 15.16B.**

Gross gamma air activity levels as a function of time at Station 4 three to eleven months after the Baneberry venting. The solid line is a least-squares fit to the data points. (Redrawn from Anspaugh et al. 1973.)

Work on resuspension has continued with measurements at NTS and Rocky Flats and experimental field work, particularly at Hanford. Some of it involved nonradioactive tracers. The reports by Sehmel (1977, 1980a,b) from Battelle-Northwest include effects of vehicular, even pedestrian traffic, breakdowns into respirable and nonrespirable sizes, etc. The results were expressed as resuspension rates (fraction per second) rather than the resuspension factor, but they can be used for the same purposes. Nonrespirable particles had resuspension rates on the order of 10^{-11} per second. Resuspension rates for respirable particles ranged from 10^{-11} to 10^{-7} per second. There was a very slow weathering half-life for these stable substances on the order of many years. A photograph of the fairly elaborate equipment used for sampling at different heights in this Battelle work is given as figure 15.17.

Work in humid environments is not as plentiful. Milham and colleagues measured plutonium resuspension and calculated the resulting dose from agricultural operations (plowing, tractor movements, etc.) in an old field at the Savannah River plant (Milham et al. 1976). The plutonium had been deposited from global fallout and atmospheric releases from the plant. They calculated resuspension factors for agricultural operations of $103 \times 10^{-8} \text{ m}^{-1}$ at a distance of 7.8 m downwind, $5 \times 10^{-8} \text{ m}^{-1}$ at 30.5 m downwind, and $24 \times 10^{-8} \text{ m}^{-1}$ at the tractor location. McLendon et al. (1976), also from Savannah River, made many

FIGURE 15.17. Measuring tracer resuspension by wind on the Hanford site. (From Sehmel 1977.)

measurements of concentration ratios for plutonium in soil and in animals, as well as uptake by plants. They also included concentrations in resuspendable material but did not calculate resuspension factors. Work at Oak Ridge has already been cited. While it is difficult to generalize, what information we have is consistent with the idea that resuspension factors will, in general, be lower in the humid southeast than in the west. However, there are many sandy areas in the east, beaches and dunes, and the chances of drought. Therefore, such a conclusion can have only general significance. For individual cases, it has been agreed that local measurements should be made whenever possible.

Despite all of the effort expended on measurements, the resuspension factor has never been entirely satisfactory for environmental situations. An obvious problem is that the numerator and denominator may have different origins. Since particles can be carried long distances by wind, the ambient air activity may, in fact frequently does, derive from soil at some distance from the point of measurement. This was made clear in the radionuclide field by some of the work from the safety shots at NTS (chapter 14). The potential lack of relationship between numerator and denominator should have been intuitively obvious, but it seemed to take many failures and much convincing to impress the problem on practicing health physicists who were anxious to have a way to predict hazard. Only when the source is large and well diffused in the environment is there a reasonable chance for measurements of surface contamination, using the resuspension factor, to be predictive.

3. Mass Loading

A different but not necessarily better approach is the so-called "mass-loading" approach. Whicker and Schultz remark on it as "perhaps the simplest." If it is

assumed that all the dust suspended in the airstream came from soil in the contaminated area, the following relation can be postulated:

$$X = MC_r$$

where

- X = air concentration in $\mu\text{Ci}/\text{m}^3$
- M = dust load of air in g/m^3
- C_r = concentration in the resuspendable fraction of the soil, in $\mu\text{Ci}/\text{g}$

M can be measured by air filters and has been a standard parameter in industrial hygiene for many years. For nonurban locations, it is about 9 to 79 $\mu\text{g}/\text{m}^3$ (mean 38), but under conditions of high winds over bare fields, it may reach as much as 1 to 10 mg of soil/ m^3 . For urban locations, it will be higher than the mean of 38 $\mu\text{g}/\text{m}^3$. The EPA uses 100 $\mu\text{g}/\text{m}^3$ for general purposes.

Estimation of C is more difficult. If the distribution of the contaminant is uniform with depth, soil samples can be sieved and the activity of different fractions measured. Frequently it is not uniform. Fresh deposits are seldom uniformly mixed, but may be confined initially to the top few millimeters of soil. This makes sampling and the problems of screening and sizing much more difficult.

The mass loading approach was given full treatment by the Los Alamos (Healy) and Lawrence Livermore (Anspaugh) people and was embraced by EPA in its draft guidance on dose limits for transuranium elements in the environment, which we will consider in a later section. It has been fairly generally agreed that the mass loading approach is not a good one for fresh deposits because of the lack of mixing with soil. However, for aged deposits, it may be useful. As described earlier, the Lawrence Livermore people set up a cascade impactor study in the GMX area of NTS and studied plutonium distribution in a seventeen-year-old deposit. Specific activity values, while not constant, did not vary greatly over the range of particle sizes measured (>7 to 0.01 to 1.1 μm), i.e., there was no obvious preferential association of plutonium with a particular particle size.

However, for fresher deposits (and this may include most of those of interest), there may be fractionation of plutonium and perhaps other radionuclides by particle size. Tamura, at Oak Ridge, whose work we met as part of the work of the NAEG (chapter 14) gave particulars for NTS, Rocky Flats, Mound Laboratory, and ORNL. Each had its own characteristic distribution of activity over the particle-size distribution (Tamura 1977). In the presence of appreciable selectivity among particle sizes, the mass loading concept cannot be applied without introducing correction factors for any skewing of the activity among the particle-size distributions.

The mass loading concept was tested by Anspaugh, Shinn, and Wilson (1974) and Anspaugh et al. (1975) by comparing measured and predicted air concentrations of a number of nuclides at several sites. The results, based upon work by a number of investigators, are shown in table 15.11.

Except for one hiatus near ground zero from one of the safety shots at NTS, the agreement between predicted and measured air concentrations is reasonably good, although the measured values seem to be lower in general. Healy (1984) comments that the mass loading approach is the only one that shows the effect of different climates on resuspension with some reliability.

TABLE 15.11. Comparison of Observed and Predicted Air Concentrations Based Upon a Single Mass Loading Model

Location	Nuclide	Air Concentration	
		Predicted ^(a)	Measured ^(b)
<i>GMX site, USAEC</i>			
<i>Nevada Test Site</i>			
NE, 1971-1972	²³⁹ Pu	7.2 x 10 ⁻³ pCi/m ³	6.6 x 10 ⁻³ pCi/m ³
GZ, 1972, 2 weeks	²³⁹ Pu	0.12 pCi/m ³	0.023 pCi/m ³
<i>Lawrence Livermore Laboratory</i>			
1971	²³⁸ U	150 pg/m ³	52 pg/m ³
1972	²³⁸ U	150 pg/m ³	100 pg/m ³
1973	²³⁸ U	150 pg/m ³	86 pg/m ³
1973	⁴⁰ K	10 ⁻³ pCi/m ³	9.8 x 10 ⁻⁴ pCi/m ³
<i>Argonne National Laboratory</i>			
1972	²³² Th	320 pg/m ³	240 pg/m ³
1972	Natural uranium	215 pg/m ³	170 pg/m ³
<i>Sutton, England</i>

^(a)Predicted value is equal to the soil concentration (activity/g) $\times 10^{-4}$ g/m³

^(b)Most values are annual averages.

Source: Modified from Anspaugh, Shinn, and Wilson 1974.

4. Resuspension Rate

A third approach to resuspension is the *resuspension rate*, described briefly in connection with the early work of Healy and Fuquay. This considers the amount of the radionuclide present on the ground that is resuspended *per unit of time* by wind or mechanical disturbance. It differs from the resuspension factor in being expressed as reciprocal time, e.g., day⁻¹. It can give the velocity of resuspension by multiplication by the ratio of activity per unit surface area and the activity per unit volume.

This approach seems to tie in most closely with the large amount of work done as early as the 1940s on wind erosion and the more theoretical aspects. Healy (1980) presents much of this background in a very detailed discussion, but could not conclude that this formulation represents the best formulation under all conditions.

5. Comment

There is still controversy over the method for calculating airborne hazards involving resuspension, but recent advances have indicated that definitive resolution may be possible soon. It does appear that the resuspension factor is the least likely to be the method of choice, despite the considerable attention lavished on it by the internal emitter establishment. Healy (1980) leans toward the resuspension rate as "our favorite method because of the capability of

integrating over a contaminated area using accepted dispersion and deposition parameters to provide concentration isopleths around the area." It is the preferred method when soil and meteorological parameters can be clearly defined. The mass loading approach gets the nod from Healy for generic studies (1984)^(a) and appears to impress the Lawrence Livermore people. It has some apparent problems, but they tend to compensate each other. The predictive success shown in table 15.11 is one reason for tempered confidence in this approach. Fortunately, meteorology, like all environmental science, is being advanced rapidly by the use of computers and modeling, which cannot help but advance soil erosion work, including resuspension by wind.

The recent series of reports by Sehmel (1981, 1983) regarding particle resuspensions and translocation on and around the Hanford site and Bikini Atoll indicate that there is much current interest in the subject. There were some experimental releases of plutonium (Sehmel 1981) to help explain some inconsistencies in the isotopic composition of some of the samples gathered on the Hanford site. Sehmel has also prepared two reviews (Sehmel 1980a,b), the first a summary of resuspension variables and a reiteration of the great uncertainty of predicting resuspension factors (range from 10^{-10} to $10^{-2}/m^{-1}$), the other specific to resuspension of transuranic elements. He also gave a full review at the DOE symposium on actinide environmental research.

C. Environmental and Population Standards^(b)

Despite considerable activity, there are only a few standards in force that can be regarded as true environmental standards in the sense that they include pathway analysis, transfer factors, and the like to at least some degree. Briefly they are:

1. Drinking Water
2. Effluents from Light-Water-Cooled Nuclear Reactors
3. Surface Contamination Standards
4. Standards for Soil Contamination
5. The Uranium Fuel Cycle
6. Transuranics in the Environment

We will take these up, in more or less chronological order, although there was considerable overlap.

1. Drinking Water

Early activities. Limits were placed on the radionuclide concentrations in air and water (maximum permissible concentrations—"MPCs") in the work place during the Manhattan Engineer District (MED) days (chapter 16). We have seen much of the applications to air in earlier chapters and earlier in this chapter. Little more needs to be added to them here. Although the limits for water were initially for water intake in the workplace and theoretically served this purpose for many years, it was soon apparent that the rigid health physics practices in the major installations severely restricted intake of contaminated water or food

(a) Remember that Healy also views with suspicion any conclusions regarding figures for the decrease of resuspension with time because of the scatter of the data.

(b) Remarks on the basis for population standards appear also in earlier sections and in chapter 16.

in the plants. The MED water limit began to have more general application, but it still was an occupational limit, not an environmental limit in the sense that it did not consider environmental pathways.

MPC values for water were included in the 1950s reports of both the NCRP and ICRP. In the 1959 reports of both organizations (chapter 16), limits for several hundred radionuclides in water were given. These were calculated from metabolic models and known behavior of each element to prevent doses to the critical organ from ever exceeding the then-extant maximum permissible exposure rate for occupational exposure. The ICRP report (Publication 2, p. 6) suggested that populations should receive one-tenth of the genetic dose or one-thirtieth of the somatic dose allowed for occupational exposure. The NCRP (Report No. 22, NBS Handbook 69, p. 6) recommended that the dose to persons in the neighborhood of controlled areas receive no more than one-tenth of the dose allowed to radiation workers and that this would generally entail control of the average concentrations in water (or air) for population exposure.

In his book on the Tri-Partite Conferences (chapter 16), L. S. Taylor introduces several documents, most of them prepared in the United Kingdom in the middle to late 1940s, that concerned radioactive contamination of drinking water (Taylor 1984, Appendices 3, 6) and the carcinogenic effects of ingested radioactive materials (Appendix 4). These were *ad hoc* calculations for specific radionuclides and are not reproduced here since the author did not see the documents until after this chapter was completed. Some of the values square well with those developed later by the more systematic approaches (chapter 16); others were very conservative indeed. Their importance for our present review is the fact that *population* standards for drinking water were considered four decades ago outside of the MED operations, partly in preparation for the postwar uses of radioactive materials. Thus, current activities are far from new, except that they concentrate less on manmade radionuclides.

When the FRC began to develop its Radiation Protection Guides, it included a recommendation for population exposure (one-tenth of the occupational levels); discussed the control of environmental radioactivity (Report No. 2, see chapters 12 and 16); and gave specific guidance for intake of ^{131}I , ^{226}Ra , and ^{89}Sr and ^{90}Sr for protection of individuals in the general population. These gave ranges for average daily intakes with the top of the middle range (Range II) corresponding to the agreed-upon dosages to the population (individual 0.5 rem/yr, or an average of 0.17 rem/yr). Despite inclusion of some detailed discussion of control of environmental radioactivity, the FRC cautioned:

Because of the wide difference in possible concentration values applying to different environmental media and depending upon specified circumstances, the Federal Radiation Council has not made any specific recommendations on such values. The responsible Federal Agencies should develop specific concentration values to apply to appropriate control actions as part of their operation criteria.
(FRC report No. 2, paragraph 1.28)(a)

It was two years before the most cognizant federal agency, the AEC, put forth specific concentration values—and these were not really tuned to specific environmental pathways, until the advent of Appendix I, as described in sections III E 3 and IV C 2 of this chapter.

(a) Much more detail of the operations of the FRC can be found in chapters 12 and 16.

The Code of Federal Regulations. Title 10 Part 20 of the Code of Federal Regulations gave two tables in its Appendix B. Table I contains concentration values for air and water for occupational exposure. Table II presents similar figures for offsite unrestricted areas. Fairly consistently, these were simply one thirtieth of the onsite occupational levels. Values were given for hundreds of radionuclides, much like the tables for occupational exposure in the ICRP-NCRP reports. Unlike the FRC's approach, which selected a few radionuclides to consider in depth, the approach in 10 CFR 20 was not specific for any given environmental pathway or set of circumstances. This lack of specificity is not surprising in view of the huge job facing the AEC and the fact that the environmental transfer phenomena reviewed in this chapter were poorly understood at the time. Thus, it cannot be said that Part 20 of Title 10 of the Code of Federal Regulations was truly responsive to the FRC's admonition quoted above. Only Appendix I in Part 50 was truly responsive, and this applied to only one type of installation, albeit an important one.

The provisions of Table II, Appendix B are still in effect for most of the hundreds of radionuclides involved, although some important ones have been selected out for individual treatment by the EPA, as we will see below, or by modifications in Regulatory Guides issued by the NRC.^(a)

The Base Broadens—Water Quality Criteria. As the extent of environmental contamination by chemical toxins and even infectious agents began to be generally appreciated, some broadly based activities began. They began in the states. For example, in the 1950s, the state of California produced a book of over five hundred pages (CAL 1952) that built upon years of earlier work throughout the world (see, e.g., Ellis 1937) concerning a large number of toxicants in water. This was expanded greatly under the California State Water Quality Control Board (McKee and Wolf 1963).

In 1966, the Secretary of the Department of the Interior sponsored a technical advisory committee to develop water quality criteria for a number of uses. These included domestic water supply, agricultural and industrial uses, toxicity of the contaminants to aquatic organisms, etc. The report (Water Quality Criteria 1968) became a basic reference for all agencies, local, state, and federal.

The organization of EPA in 1970 (see chapter 11 and 1972 amendments to the Water Pollution Control Act) transferred broad responsibilities for water quality to the new agency. Under a contract with the NAS-NRC and the National Academy of Engineering, a report giving broad criteria for water quality was produced (NAS-NRC 1972). This was followed by an extensive EPA compilation entitled "Quality Criteria for Water" (EPA 1976b). Criteria were spelled out for several uses and for a large number of chemicals and other potential pollutants.

These criteria did not include radionuclides, since these were still considered the domain of AEC and its successor agency ERDA.

The Safe Drinking Water Act of 1974—Interim Drinking Water Regulations. The above act gave the administrator of EPA authority over the quality of drinking water in public water systems and called for the speedy production of National Interim Drinking Water Regulations. Another contract was let and a report was

(a) A thorough revision of Title 10 of the Code of Federal Regulations is now in process by the NRC.

prepared by the NAS-NRC to set the pace. However, the proposed regulations were published by the EPA in the *Federal Register* well before the NAS-NRC report was issued. Those for microbiological and chemical contaminants were put out for discussion and comment on March 14, 1975 (EPA 1975b); those for natural and manmade radioactivity followed on August 14, 1975. It was proposed that they be incorporated in Part 40 CFR 141 and be effective at a suitable date after the NAS-NRC report had been issued and after a suitable period for public comment.^(a)

For naturally occurring radionuclides, attention was focused on ^{226}Ra and ^{228}Ra and gross alpha-particle activity (including ^{226}Ra). The proposed levels were:^(b)

Combined ^{226}Ra and ^{228}Ra	5 pCi/l
Gross alpha-particle activity (including ^{226}Ra)	15 pCi/l

For manmade radioactivity, the proposal suggested an annual concentration of beta-particle and photon activity in drinking water that would not produce an annual dose equivalent to total body or any internal organ greater than 4 mrem.

Calculations were given for the limiting annual concentrations that would produce this dose for only two nuclides. These were:

Tritium	Total body as critical organ	20,000 pCi/l
^{90}Sr	Bone marrow as critical organ	2 pCi/l

There was much discussion of the costs involved, for it seemed clear that many public water supplies (estimated then at about five hundred community water systems) did not meet the proposed radium standard. The necessary means for clean-up were discussed, including prominently the application of the ion exchange techniques used in water softeners.

The figures were based on estimates of risk using the linear no-threshold concept for dose-effect relationships (chapter 16). For the radium limit, the associated risk was estimated at 0.7 to 3 fatal cancers annually per million exposed persons. The corresponding risk estimates for the 4 mrem/yr proposed for manmade radiation were calculated as 0.4 to 2 cases per million exposed persons per year. The document also indicates that the 4 mrem/yr is not likely to be exceeded by sources currently in existence (deposited fallout radioactivity and effluents from other sources). There is no discussion of the validity of the choice of risk made in comparison to other risks of existence. Much more detail was given in an EPA document entitled *Statement of Basis and Purpose for the Proposed National Interim Primary Drinking-Water Regulations* dated August 15, 1975, but not numbered or otherwise identified. For written comments and a public hearing, the EPA requested, especially, further information on such things as number and location of public water supply systems that would be affected, the numbers that would require radium analysis, etc.

(a) EPA noted that the PHS limits then in use were enforceable only for interstate carriers of drinking water and for contaminants causing communicable diseases.

(b) Surface-water supplies ordinarily contain little radium. Thus, these limits for practical purposes applied primarily to ground-water supplies.

Reactions to these proposals were quite sharp. The Energy Research and Development Administration (see, for example, Gossick 1975) contended that present radiation standards for drinking water supplies were adequate. The average annual dose from natural background on the order of 130 mrem at sea level made the limitation of potable water to 4 mrem seem absurd to ERDA and the costs to many small communities out of proportion to the health effects prevented. There was a sizeable feud between the two federal agencies on this subject.

Robley Evans (chapter 1) addressed a strong letter that contained, briefly, the following points (Evans 1975):

1. There are many water supplies with ^{226}Ra values between 10 and 36 pCi/l. These supply a total population of over 30,000 persons in nineteen cities. Careful epidemiologic studies have revealed no deleterious (or beneficial) health effects in these populations.^(a) Furthermore, over 400,000 persons consume water with more than 4 pCi/l of ^{226}Ra , again with no demonstrable health effects.
2. The daily intake of water is more like 1 l/day than the 2 l used in the calculations.
3. Measured body burdens of radium in subjects existing under the current 30 pCi/l limit (see ICRP) are well below those associated with measurable effects, i.e., about 0.001 μCi versus the accepted limit (occupational) of 0.1 μCi .
4. The linear no-threshold relationship does not apply to radium in humans (see chapter 1 for Evans's many papers on this subject).
5. The retention of radium is not well represented by an exponential function of time. A power function (the Norris equation—see chapter 1) is considered a better description, and its use supports a higher MPC in water.
6. A quality factor (chapter 16) of 10 is too high for radium. It should be 3 (chapter 1).
7. No evidence is presented that indicates problems with the limits promulgated by ICRP, NCRP, and FRC.
8. Gross alpha measurements should be in counts per minute, not pCi.

There was more in the Evans letter, but the above is enough to present his arguments. Evans suggested that the supplies that currently run above 5 pCi Ra/l be given variances until the standards could be reconsidered, particularly since the economic costs were, in his view, inflationary.

In 1976, the EPA published "Drinking Water Regulations—Radionuclides" in the *Federal Register* (EPA 1976b).^(b) It reviewed the responses, made some changes in detail, but retained the maximum contamination levels as proposed, except that the calculated level for ^{90}Sr associated with 4 mrem/yr became 8 pCi/l rather than 2 pCi/l. The regulations went into effect on June 24, 1977.

(a) More detail on these supplies and the investigations are contained in chapter 1.

(b) In the next year, the NAS-NRC produced a set of recommendations to EPA under the title, *Drinking Water and Health* (NAS-NRC 1977).

There has continued to be opposition to the levels chosen and requests for reconsideration (e.g., Evans 1980), but, except for polite responses reiterating the EPA positions (e.g., Cothorn 1980), no substantive changes have occurred.

At the 1982 meeting of the Health Physics Society held at Las Vegas, Henry Lucas, from ANL and an old hand at the study of radium in drinking water, gave a paper on ^{226}Ra and ^{228}Ra in drinking water (Lucas 1982). He cited measurements from more than 90% of the communities in Illinois, Iowa, Missouri, and Wisconsin that obtained drinking water from wells that penetrate into deep sandstone aquifers and have relatively high radium contents. There were 117 communities with a total population of 1,442,000 that used water with ^{226}Ra concentration greater than 3 pCi/l and 91 communities with a population of 599,000 that regularly consumed water exceeding 5 pCi/l. He did not comment, as did Evans and as we saw in chapter 1, that no health effects had been found.^(a) He did comment on some anomalous variations in the ^{226}Ra - ^{228}Ra ratio that required further investigation.

The 1977 water standards specifically excluded radon and uranium. In 1981, EPA circulated a draft of "Suggested Action Guidance" (SAG)^(b) for uranium in drinking water (EPA 1981a). The level suggested was 10 pCi uranium per liter as an *upper limit* on the basis of radiation carcinogenesis and kidney damage. The radiotoxicity derivation used the ICRP Publication 30 model for uranium metabolism and EPA life table estimates of radiation effects. The postulated effect was based entirely on calculated dose. To date, there have been no cancers known to be associated with natural uranium except those described in animals at very high doses (chapter 2). For kidney toxicity, it was quoted that deleterious effects have been seen down to "dose rates" on the order of 0.1 mg/kg.

At the same Las Vegas meeting of the Health Physics Society mentioned above, two of EPA's principal workers with standards for radionuclides in water, William L. Lappenbusch and C. Richard Cothorn, enlarged upon the proposed criteria for uranium (Lappenbusch and Cothorn 1982).^(c) They stated that surface, ground, and domestic waters in the United States "seem to average 1, 3 and 2 pCi/l respectively of natural uranium." The Oak Ridge National Laboratory made some estimates for EPA of communities in this country that were above these averages. Some 64,000 community water supplies were measured. Of these, 25 to 650 exceed 20 pCi/l, 100 to 2,000 exceed 10 pCi/l, and 2,500 to 5,000 exceed 5 pCi/l. Lappenbusch and Cothorn proposed review of the implications of these facts vis-à-vis their proposed uranium standard at a national workshop for radioactivity in drinking water scheduled for late 1982. One was actually held in 1983 and is described briefly below.

In response to proposals for ground-water regulations in the state of New Mexico, Evans (1976b, 1981) referred to chapters 1 through 5 of the *Handbook of Experimental Pharmacology* edited by Hodge, Stannard, and Hursh (referenced in chapters 3, 9, 16, and elsewhere) and the 1975 Conference on Occupational Health Experience with uranium, also referenced earlier. The facts reemphasized that chemical toxicity of uranium should be the basis for control

(a) It is a moot question whether or not the search was sufficient or the populations were large enough to support an epidemiologic study.

(b) EPA-SAGs are not legally enforceable standards but advisories.

(c) The same meeting and same issue of *Health Physics* (Vol. 43, No. 1) contained several other papers regarding radionuclides in drinking water.

and that accepted levels for chemical toxicity are much higher than the 0.1 mg/kg quoted by EPA. The calculated water levels would be 1,200 pCi U/l using the EPA-SAG definition of the curie of uranium and the accepted level for threshold kidney damage (3 mg/kg).

The pot seems to still be boiling on water standards. The national workshop on radioactivity in drinking water was held under EPA auspices at Easton, Maryland, on May 24-26, 1983. It examined all aspects for radium, radon, and uranium in drinking water through seven specialty committees but limited itself to natural radioactivity. The proceedings of this workshop have appeared (Cothern and Lappenbusch 1985). It contains a full review of the EPA's activities and present position (Lappenbusch and Cothern 1985). What the final outcome will be regarding standards for drinking water can only be conjectured. The comprehensive paper by Wrenn et al. (1985) gives a new metabolic model for uranium and radium, and tentative limits of 100 $\mu\text{g/l}$ for uranium in drinking water. They also suggest relaxation by a factor of four for the radium limit.

2. Effluents from Light-Water-Cooled Nuclear Reactors

This was the earliest limit to include the vectors of food pathways as discussed earlier in this chapter (section III E 3).^(a) It is contained in Appendix I^(b) of the Code of Federal Regulations (10 CFR 50). It is still in force and is considered to have functioned very well in preventing any undue population exposures from this source in normal operations. The basic provisions of Appendix I are repeated below for the reader's convenience.^(c)

- a. The calculated annual total quantity of all radioactive material above background to be released to the atmosphere for each light-water-cooled nuclear power reactor should not result in an estimated air dose . . . in unrestricted areas in excess of 10 mrad of gamma radiation or 20 mrad of beta radiation.
- b. The Commission^(d) may specify as guidance on design objectives a lower quantity of radioactive material, e.g., annual external dose from gaseous effluents to any individual in an unrestricted area of not more than 5 mrem to the total body or 15 mrem to the skin.
- c. The calculated annual total quantity of all radioactive iodine and radioactive material in particulate form released from each light-water-cooled nuclear reactor shall not result in an annual dose or dose commitment from *all pathways of exposure* in excess of 15 mrem to any organ.
- d. The calculated annual total quantity of ^{131}I in gaseous effluents shall not exceed 1 Ci for each light-water-cooled nuclear power reactor at a given site.

These limits were originally set by the AEC and are now applied by the NRC, although the NRC is busy revising the applicable parts of the Code of Federal Regulations; and some details may be changed. It seems likely that the control by environmental pathways will continue to govern this segment of the nuclear power enterprise.

(a) Discussion of derivations was given there also.

(b) Note again that this is the letter I not a number.

(c) These were paraphrased from the Code of Federal Regulations.

(d) The NRC.

3. Surface Contamination Standards^(a)

We saw (chapter 14) that an important reason for the safety shots with plutonium, such as Test Group 57 and Operation Roller Coaster, in the late 1950s and early 1960s, was to test the validity of the rather arbitrary guidelines set up by the military in the event of a contaminating incident, e.g., a "Broken Arrow."^(b) For many years, the military had a fairly elaborate set of guidelines for denying or restricting access, or allowing regular living activities, etc., on the basis of radioactivity at the soil surface. Most of them were and are in procedural manuals and are classified, but some can be discussed.

In 1956, the Los Alamos people (Harris et al. 1956) suggested that an initial contamination level after the event of $100 \mu\text{g}/\text{m}^2$ ($6 \mu\text{Ci}/\text{m}^2$) of ^{239}Pu was realistic for lifetime occupancy. It will be recalled (chapter 14) that one of the objectives of Test Group 57 in Operation Plumbbob, in 1957, was to test the validity of this line and that contours for animal exposures were placed nominally at 10, 100, and $1,000 \mu\text{g}/\text{m}^2$. The results of this test could hardly be construed as validating or negating the validity of these levels. Yet, soon after publication of the reports from Test Group 57, and allegedly based on them, we find an emergency level of $1,000 \mu\text{g}/\text{m}^2$ being proposed as the line at which access to an area would be denied.^(c) This was in the classified literature for a while (Dick 1972, 1982; Boecker 1972),^(d) but saw fairly wide distribution later.

In 1958, the Air Force Special Weapons Center issued a technical note concerning aircraft accidents involving plutonium contamination (Baker, Boecker, and Dick 1958), which gives one standard for soil, $1,000 \mu\text{g}/\text{m}^2$ ($61 \mu\text{Ci}/\text{m}^2$), and one for air, $1,000 \text{ d}/\text{min}/\text{m}^3$. It gives procedures to use, areas potentially involved, etc., but no discussion of the basis for the limits. A bit more was contained in a report from the Test Group 57 work (Dick and Baker 1961).

In the same year, a manual was produced under the Defense Atomic Support Agency (DASA 1961) that gives time of occupancy factors for areas contaminated to different levels and also permissible surface contamination levels for conditions producing different resuspension factors. Lifetime occupancy was considered compatible with initial^(e) ground concentrations of ^{239}Pu of $1,000 \mu\text{g}/\text{m}^2$ or less, an indeterminate period when it was $3,000 \mu\text{g}/\text{m}^2$, 8 days when it was $4,000 \mu\text{g}/\text{m}^2$, and 3.6 days at $5,000 \mu\text{g}/\text{m}^2$. The derivation of these figures is not given, except it appears that a resuspension factor of $10^{-6}/\text{m}$ was employed.

The permissible surface levels at different resuspension factors were calculated as shown in table 15.12.^(f)

- (a) This discussion refers entirely to surfaces in the environment, not interior surfaces that are regulated to much lower levels. Also, it is limited to plutonium, since that is where the emphasis has been placed. Levels for a few other substances were considered, but they are not numerous.
- (b) Nonnuclear detonation involving the crash of an aircraft carrying a nuclear weapon.
- (c) This is, of course, not the same operation as allowing lifetime exposures as proposed for the $100 \mu\text{g}/\text{m}^2$ line. It was an emergency level.
- (d) I am greatly indebted to these former Air Force officers for personal communications and copies of unclassified reports on this subject.
- (e) Remember that these levels referred to a single event and to the initial contamination.
- (f) The reproduction of this and other figures from military documents should be regarded as illustrative only, primarily to show what was done. The standards actually used tended to be site-specific, and details have been revised many times since the work quoted above was done.

TABLE 15.12. Maximum Initial Surface Contamination Levels Under Various Conditions

Conditions of Dust Production (dry surface)	Resuspension Factor	Permissible Surface Contamination ($\mu\text{g}/\text{m}^2$) ^(a)
Vehicular traffic (Nevada)	7×10^{-5}	10
People working or active in a closed area	4×10^{-5}	20
Dirty rural, suburban, and metropolitan atmosphere	7×10^{-6}	100
People working or active in an open area	2×10^{-6}	360
Isolated area where basically only relatively low-velocity wind is the resuspending force and people are taking great care to prevent resuspension	$\sim 7 \times 10^{-7}$	1000 (100 dpm/m ³)

(a) As plutonium.

Source: Modified from Report LA-2079 via DASA 1961 (see footnote f, p. 1343).

In view of the evanescent nature of the resuspension factor and its questionable validity, it is unlikely that these recommendations were applied very conscientiously. Indeed, especially since these are applications for emergency conditions, there has been a tendency to assume some single "reasonable" level for resuspension and apply a single set of controls.

Probably the most ambitious undertaking in this manual was a graph relating exposure time to surface activity in $\mu\text{g}/\text{m}^2$ or dpm/m³. This is reproduced as figure 15.18.

FIGURE 15.18. Airborne plutonium contamination hazard estimated from surface activity (dry), assuming a resuspension factor of 4×10^{-6} . (Redrawn from a DASA manual [DASA 1961] that brought it over from some general procedures for Special Weapons Accidents [see footnote f, page 1343].)

It is not clear to what extent such a graph was ever used, except for planning. However, it is interesting in its demarcation of "major," "nominal," and "minimal" hazard and also by requiring respiratory protection along a line at one-tenth of the maximum permissible limit.

In 1968, Kathren of Battelle-Northwest, produced a general review of the status of surface contamination levels for environmental plutonium (Kathren 1968). This is quite complete on the environmental behavior of plutonium, in its review of the several recommendations extant, and in derivation of acceptable interim standards. Indeed, it raised some eyebrows by bringing into the open literature some regulations that, while no longer classified for security purposes, had not received much general distribution. He also uncovered confusion and inconsistencies by listing maximum permissible alpha contamination standards for the workplace in many countries around the world and some of the environmental levels in use. These include U.K. figures of $0.1 \mu\text{Ci}/\text{m}^2$ for "inactive" areas and $1 \mu\text{Ci}/\text{m}^2$ for "active" areas, the U.S. Department of Defense (DoD) level of $62 \mu\text{Ci}/\text{m}^2$ ($1,000 \mu\text{g}/\text{m}^2$), and Navy Publications (from the NRDL) that give $0.04 \mu\text{Ci}/\text{m}^2$ for unrestricted release (Sulit, Leahy, and Baietti 1961), and other Navy publications suggesting $0.62 \mu\text{Ci}/\text{m}^2$ for shipboard occupancy on a continuous basis (Schwab 1958; Leahy and Smith 1958).

Kathren calculated his own maximum permissible surface contamination levels for environmental plutonium. These were based on an allowable dose of 1.5 rem/yr to lung or pulmonary lymph nodes (approximately $3.2 \times 10^{-5} \mu\text{Ci}$ in pulmonary lymph nodes).^(a) The calculated values are given in table 15.13.

TABLE 15.13. Interim Maximum Permissible Surface Contamination Levels for Environmental PuO_2

	Average	Maximum
Urban, suburban, and recreation areas	10^3 dis/min per 100 cm^2 ($0.04 \mu\text{Ci}/\text{m}^2$)	10^4 dis/min per 100 cm^2 ($0.4 \mu\text{Ci}/\text{m}^2$), spread over $\leq 10\%$ of the total area included
Rural: truck farming, annual food crops, grazing land, milk-shed, etc.	10^4 dis/min per 100 cm^2 ($0.4 \mu\text{Ci}/\text{m}^2$)	
Rural: deep root perennials (e.g., nuts, certain fruits)	10^5 dis/min per 100 cm^2 ($4 \mu\text{Ci}/\text{m}^2$)	
Remote or Controlled: desert, forest, fenced or limited access areas	10^6 dis/min per 100 cm^2 ($40 \mu\text{Ci}/\text{m}^2$)	

Source: Modified slightly and reset from Kathren 1968.

For these calculations, Kathren used an air concentration half-life of 45 days (see above); a resuspension factor of 10^{-4} m^{-1} ; a particle size distribution of $2 \mu\text{m}$ mass median diameter with $\sigma_g = 1.5$; 20% deposition in the pulmonary compartment with 15% of this going to pulmonary lymph nodes; transfer half-life from lung to lymph nodes of 360 days; and a mass of 20 g for the pulmonary lymph nodes.

(a) Praise be, the entire derivation is given!

Obviously, these figures are more conservative than those used at the time by the military^(a) and are in line with ICRP-NCRP conventions, except for the use of pulmonary lymph nodes as "critical organ." Again it is doubtful if such a spread, i.e., $0.04 \mu\text{Ci}/\text{m}^2$ to $40 \mu\text{Ci}/\text{m}^2$ would be applied operationally instead of a single limit, but it gives flexibility if it is needed. This author finds no records of these limits having been adopted, as such, for use by the military or the regulators.

A comprehensive consideration of plutonium surface contamination levels for DoD action appeared in 1972 (DASA 1972). This report, seen only in draft form and classified "Official Use Only," presents the entire story again. It points out that all federal guidelines (i.e., DoD/AEC [Weapons Accident], U.S. Army, U.S. Navy, and U.S. Air Force) except AEC, use $1,000 \mu\text{g}/\text{m}^2$. No AEC limits for environmental decontamination had then been stipulated per se, but DASA inferred from parts of 10 CFR that they would be $5.6 \mu\text{g}/\text{m}^2$ as derived from indemnity agreements and $0.96 \mu\text{g}/\text{m}^2$ on the basis of permitted effluent releases to controlled areas and application of a resuspension factor of 10^{-6} m^{-1} .^(b)

After much discussion, the DASA report suggested three levels, each an order of magnitude apart, à la Test Group 57. These ranged from $50 \mu\text{g}/\text{m}^2$ for residences and urban areas; through $500 \mu\text{g}/\text{m}^2$ for rural farmland, grazing land, etc.; to $5,000 \mu\text{g}/\text{m}^2$ for remote, limited access or controlled areas. No derivations are given, although the lifetime organ doses are given for several organs at eight different levels. The maximum is 34 rad to the lymphatic system at $5,000 \mu\text{g}/\text{m}^2$ and the minimum 0.001 rad to bone at $5 \mu\text{g}/\text{m}^2$.

A personal communication from DASA, received while the above was still in draft form, indicated that the final version would present only one recommended level for action and that this would be $50 \mu\text{g}/\text{m}^2$. It has not been possible to determine whether or not this much more conservative figure has come into general use in the DoD.

Throughout these discussions, the proper choice of resuspension factor comes up for discussion. The consensus seems to settle on 10^{-6} m^{-1} for generic and most other uses. Fortunately, except for Palomares and Thule and a few unpublicized incidents, there has been little need to apply these ground contamination criteria. It is clear that some of the transfer factors under discussion in this chapter played a role in their derivation, but details, except for the Kathren work, are hard to come by.

4. Standards for Soil Contamination

The need for clean-up of former sites of radium, uranium, and related extraction and refining operations stimulated much work on the development of criteria for such enterprises. In chapter 11, we reviewed activities of the Oak Ridge Environmental and Health Physics groups in surveying over one hundred sites and helping to orchestrate their clean-up. As noted there, some of the sites were quite old and had long since been turned back to the public domain. Others were quite new in the sense that contaminated soil had been used for construction, etc.

(a) Because of the differing assumptions used, the relative doses cannot be calculated directly, but obviously only the highest level, $40 \mu\text{Ci}/\text{m}^2$ approaches the $62 \mu\text{Ci}/\text{m}^2$ used by the military.

(b) Allowable surface contamination levels for transportation are considerably lower.

A good statement of the problem and potential solution appeared in the EPA's preamble to its generation of standards for 40 CFR Part 192 (FR 1980a) and is quoted below:

Lands and buildings contaminated with uranium mill tailings pose risks to public health. The greatest hazard from tailings on open land is increased levels of radon decay products in buildings. When radon decay products are inhaled, they increase the chance of lung cancer. Exposure to direct gamma radiation and contamination of drinking water and food may also occur.

Tailings usually only pose significant risk to people who are exposed for a long time. However, some homes and other buildings have been found in which the radon decay product concentration is quite dangerous. There are such buildings, for example, in Salt Lake City, and in Canonsburg, Pennsylvania. Several buildings in Salt Lake City are immediately adjacent to a tailings pile, or have tailings in, under, or around them. In some of these, indoor radon decay product concentrations exceed the average occupational concentration limit for uranium miners (0.3 WL). Included among these is a fire station in Salt Lake City, where substantially elevated levels have been measured even when mechanical ventilation is used. In Canonsburg, an industrial park is now located on an inactive processing site. Eight buildings leased to commercial tenants are located directly over heavily contaminated land. Measurements during working hours show that all buildings have substantially elevated indoor radon decay product concentrations, with the highest average daytime level being 0.4 WL. These levels are dangerous and will continue. To allow DOE to begin remedial action under Pub. L. 95-604 to alleviate these hazards, we have decided to promulgate these immediately effective interim cleanup standards.

Studies of indoor background radioactivity in Grand Junction (Colorado), New York State, and New Jersey show that at least 10 per cent of houses with basements exceeded the interim standard's remedial action level of 0.015 WL. Because of this, we believe it would often be impossible to try to reduce levels for houses affected by tailings significantly below 0.015 WL by removing the tailings. Thus, it is unlikely that the final standards will be set at a level significantly more stringent than the interim action level of 0.015 WL, and remedial actions performed under the interim standard will not have to be redone. Furthermore, although we have not formally solicited public comments on the interim standards, the Nuclear Regulatory Commission and the Department of Energy have been consulted. For these reasons, we believe issuing immediately effective interim cleanup standards is justified.

Obviously, the story started long before this. While Oak Ridge was involved deeply with the operations,^(a) it was Los Alamos that was most consistently involved with the criteria and standards. As early as 1971, Jack Healy prepared a Los Alamos report on decision levels for surface contamination (Healy 1971). This did not particularly concern the general environment. It considered dose to the skin and possible inhalation or ingestion of material deposited on skin or clothing or in the home and possible transfer by resuspension. Over 180 isotopes were considered. It may well be that this research stimulated Healy's interest in general environmental contamination (or the interest may have already been present). In any event, he continued in the field and is still at it, as we saw in the previous section. In 1972, Healy circulated, within Los Alamos, a draft document for a plutonium-in-soils standard that set the pattern for his later work. By 1974, he proposed an interim standard for plutonium-in-soils (Healy 1974). He reviewed skin absorption, ingestion, inhalation, resuspension, contamination of clothing and of dwellings, and suggested provisional upper

(a) The surveys of previously utilized sites, mill tailings, etc.

limits for soil contamination.^(a) He derived the standards from extant recommendations for body burden and annual dose limits for population groups and individuals (ICRP 1966).^(b) This implied a maximum body burden of $0.004 \mu\text{Ci}$ of ^{239}Pu and a maximum lung burden of $0.0016 \mu\text{Ci}$. He also applied the Radiation Protection Guides of the FRC (chapter 16) and their ideas for Protective Action Guides. Healy reviewed the problems of applying soil limits based on amounts per unit surface area as was done for the limits described in the previous section, particularly the uncertainties in the depth of the soil layer to be sampled or considered significant. As a result, he presented his calculations on the basis of either the concentration in soil or the quantity per unit of surface area. Standards were thus derived that could be used on either basis. The operators could determine which to use according to the information they had available and what they felt most comfortable with.

After thorough consideration of each entry route and each step from soil to lung, including intake factors, Healy suggested interim standards for plutonium in soils as shown in table 15.14.

TABLE 15.14. Recommended Interim Standards for Plutonium in Soils

	In <100 μm Particle Size Fraction			Total**		
	D/M per g	$\mu\text{Ci/g}$	$\mu\text{Ci/m}^2$	D/M per g	$\mu\text{Ci/g}$	$\mu\text{Ci/m}^2$
Top 0.1 cm*	500	2×10^{-4}	0.4	1000	4×10^{-4}	0.8
Any one cm layer	500	2×10^{-4}	4	10000	4×10^{-4}	8

*For bare soil or areas with sparse vegetation. Where area is reasonably well vegetated (greater than 50% of the area is covered with low vegetation) and a reasonable root mat exists to hold the soil, the concentration listed can be applied to a 0.5 cm layer which would permit up to $2 \mu\text{Ci/m}^2$ in this layer.

**With the provision that the fraction with the particle sizes less than $100 \mu\text{m}$ is known not to exceed the limits given. If this is not known, the values for the $<100 \mu\text{m}$ fraction should be applied to the total.

Source: Reset from Healy 1974.

Note that the table gives not only both concentration and surface area bases, but the numbers are divided into two fractions according to the particle size measurements. The fraction larger than $100 \mu\text{m}$ was arbitrarily chosen as supporting a limit exactly equal to that below $100 \mu\text{m}$, and the total was thus twice that associated with the lower range. Limiting soil concentrations were also given for casual and deliberate^(c) ingestion, skin absorption, and several varieties of inhalation exposure.

(a) The lower limits were based on the ALARA principle.

(b) For details see chapter 16 and the review by Langham and Healy (1973). The body and lung burden figure is one-tenth of the limit for workers.

(c) This means "pica," the deliberate ingestion of dirt by children at play and is pegged a factor of ten lower because of the possibly greater absorption of plutonium from the gut in the very young and their potentially greater radiosensitivity.

Still later, Healy prepared a draft report examining the pathways from soil to man for plutonium (Healy 1976a). This was published as a Los Alamos report (Healy 1976b) and in an NAEG report in 1977 (Healy 1977). Pica in children and mechanical resuspension were more limiting than wind resuspension. Also, ingestion of foodstuffs containing plutonium could become an important pathway if all of the food was produced in the contaminated area, a fairly unlikely situation for most environments currently contaminated with plutonium.

In 1979–1980, the field broadened from plutonium to radium, uranium, other transuranics, and other relatively long-lived radionuclides such as ^{90}Sr and ^{137}Cs . In 1979, Healy and colleagues prepared a Los Alamos report entitled *Interim Soil Limits for D&D Projects* (Healy, Rodgers, and Wienke 1979). The suggestions were considered as tentative and preliminary partly because the expense of the clean-up operations could mount rapidly with relatively small decreases in the level to be aimed at. Also, a dilemma was posed in preparing these because the EPA was developing its proposed guidance for transuranium elements in the environment, to be discussed in the next section. They were suggesting limits based on doses of 1 mrad/yr to lung and 3 mrad/yr to bone for the alpha particles of transuranium nuclides. By contrast, the extant FRC guidelines were 0.5 rem/yr.^(a) Healy chose to utilize the latter since the EPA proposals were still in the review stage. The difference in clean-up levels is substantial.

The recommended soil limits in the Los Alamos report were as shown in table 15.15. Details of the many choices made are given in the text of the report. Note that a preliminary radium standard is cited. This is referenced in the bibliography for this chapter (viz., Healy and Rodgers 1978).

TABLE 15.15. Recommended Soil Limits^{a,b} (In pCi/g)

	Inhalation	Ingestion		External Radiation	All Pathways ^c
		Home Gardener	Full Diet		
^{231}Pa	50	740	150	250	40
^{227}Ac	2,000	4,900	1,000	300	250
^{232}Th	45	670	140	40	20
^{228}Th	1,000	37,000	7,800	55	50
^{230}Th (No Daught.)	300	4,400	940	36,000	280
^{238}U – ^{234}U	750	44	8	6,000	40
^{90}Sr	2×10^6	100	19	—	100
^{137}Cs	7×10^6	800	1	90	80

^aSoil limits for ^{241}Am and $^{239,240}\text{Pu}$ are available from EPA recommendations, and a soil limit for ^{226}Ra has been reported by Healy and Rodgers.

^bLimits are to apply to only one nuclide present in the soil. If more than one is present a weighted average should apply.

^cBased on diet of a home gardener.

Source: Reset from Healy, Rodgers, and Wienke 1979.

(a) Note rem, not rad.

Naturally, these Los Alamos standards were unofficial since they had not been through the *Federal Register* or other approval processes. Yet, they appear to have been used, informally at least for some clean-up operations. They are still under consideration by organizations such as the NCRP.

An important aspect of these and other soil standards is the choice of factor for gastrointestinal tract absorption. As we have already seen, there has been a tendency to apply larger absorption factors to very low-level long-term intakes, than to figures used for occupational exposures. Thus, Healy used a gastrointestinal absorption factor of 20% (0.2) for uranium instead of the 0.05 for water soluble forms (valence + 6) or 0.002 for insoluble salts (valence + 4) used for calculation of occupational standards. Such a change could, of course, make a significant difference (and did) in the criteria for clean-up. Healy prepared an informal survey of all the data on absorption of transuranium elements from the gastrointestinal tract as an appendix to another Los Alamos report (LA-UR-79-100 Excerpt) to document the choice of absorption figures and also circulated the compilation.

By this time, the EPA was assuming a central role. Fortified by provisions of the Atomic Energy Act and the Presidential Reorganization Plan No. 3 of December 1970, the agency proposed standards for plutonium in soils and for the clean-up of both older plant sites such as those described in chapter 11 and above, and for uranium mill tailings.

The formal development of general federal standards for plutonium in soils began in 1974 with an announcement in the *Federal Register* followed in 1976 by enormous documents entitled *Draft of Federal Guidance for the Environmental Limits of Plutonium Contamination in Soils*. These documents cited incidents of old and new contamination, criteria for derivation of risk, sampling and analysis methods, and anticipated impacts in addition to the proposed regulations. In line with the trend of the times to base limits on estimates of risk, the agency took the view that total risk should not exceed 10^{-4} to 10^{-5} /yr. They also took the view that no single activity should be permitted to contribute more than one one-hundredth to one one-thousandth of the basic radiation protection guide. For lung, with a proposed general population limit of 1.5 rem/yr, the allowance for an individual would thus be 2 to 15 mrem/yr, which equated to a risk of 10^{-6} to 10^{-7} /yr. They chose 10^{-6} for the most exposed individual.^(a)

The actual proposed limit for plutonium contamination in soils was based upon inhalation of suspended soil particles. It came out, after many tortuous calculations and sets of assumptions, to 25 dpm/g of soil for a sample constituting a 1-cm depth, or $0.2 \mu\text{Ci}/\text{m}^2$. The agency went to considerable pains to point out that the proposal was limited to contaminated soils, was not concerned with release limits from facilities, nor was it intended to supersede existing radiation protection guides. It was intended "only to supplement existing guides by specifying limits for one single source of activity from one group of radionuclides within broader limits." The equating of the soil concentration to lung dose was far too complex to be reproduced here. Suffice it to say that several new factors were introduced, such as an "Area Concentration Factor," and an "Enrichment Factor," and others, as well as choices regarding resuspension factors (or mass loading), etc.

(a) This is equated in one section of the report to 15 mrem/yr to the lung, but the final guidance gives 10 mrem as the maximum individual dose from this source.

One needs only to look at the final figures to expect that these tentative proposals would generate much opposition. The basic methodology was considered an advance by many, but the solidity of many of the "constants" that had to be cranked in was seriously doubted. The review process took many months. The ideas returned later in two forms—limits for clean-up of sites and a more general document on environmental radiation protection for normal operations of the uranium fuel cycle. We will review the latter in the next section. The clean-up standards took off in a slightly different direction. While they were concerned with radium and the actinides, they focused more on the risks of lung cancer from radon decay products and of fatal cancer from whole-body exposure to external gamma radiation. Indeed, it was the mill tailings issue that they aimed at most vigorously. The standards were described in the *Federal Register* in April 1980 (FR 1980a,b) and were to be implemented as part of the Code of Federal Regulations (40 CFR 192). This took place on September 30, 1983, as 40 CFR 192, parts D and E.

The figures, couched in terms of levels at which remedial action must begin, were as follows:

1. Average concentration of ^{226}Ra attributable to residual radioactive material from any designated processing site in any 5-cm thickness of soils or other materials within one foot of the surface, or in any 15-cm thickness below one foot, shall not exceed 5 pCi/g.
2. The levels of activity in any occupied or occupiable building shall not exceed an annual average indoor radon daughter product concentration of 0.015 Working Levels, including background, or an indoor gamma radiation rate of 0.02 milliroentgen per hour above background.

Note that these are for inactive sites. While EPA proposes the standards, DOE has the job and expense of clean-up. Currently, active sites are governed by the fuel cycle standards we will consider in the next section. Specific guidance for them is reported to be in preparation.

Many view these limits as too low and as putting an unnecessary burden on those who must pay for the clean-up.^(a) EPA appears to take the view that its environmental standards must be low since they cover only one pathway at a time, i.e., only a portion of the total risk to an individual in the population or an average for the population.

5. The Uranium Fuel Cycle

This is a long story and one we have not considered in any depth heretofore. Therefore, we must review it here. The standards are contained in 40 CFR 190 and were approved in two parts. Part A, which was proposed to go into effect on December 1, 1979, gives a blanket limit of 25 mrem/yr to whole body or any individual organ, except thyroid, which was allowed 75 mrem/yr. Part B concerned the total quantities of radioactive materials allowed to enter the general environment per gigawatt of electrical energy generated. These were:

1. less than 50 Ci of ^{85}Kr
2. less than 5 Ci of ^{129}I
3. less than 0.5 Ci of ^{239}Pu and other alpha-emitting transuranium radionuclides with half-lives greater than one year.

(a) There were also many questions of scientific basis and derivations.

The effective date for ^{85}Kr and ^{129}I was proposed to be January 1, 1983, to give time for the industry to install equipment and devise mechanisms for meeting these criteria. The guidance was addressed to federal agencies.

Note that these standards were expected to apply to all operations within the uranium fuel cycle. Thus, like the estimates of dose from the uranium fuel cycle, discussed earlier, they apply to milling, conversion, enrichment, fuel fabrication, light-water-cooled reactors, fuel reprocessing, and transportation of radioactive materials in connection with any of these operations. The standards were calculated to reduce the total potential health impacts, i.e., cases of cancer, leukemia, and serious genetic effects in human populations by one thousand or more.

Obviously, monitoring operations as extensive and diversified as those named above and measures to insure that neither the broad limits of radiation dose nor the maximum permissible releases were exceeded posed a Herculean task that was not shouldered without protest. The history is capsulized below.

In May 1975, the Office of Radiation Programs of EPA circulated a draft environmental statement outlining the proposed radiation protection requirements for normal operations of the uranium fuel cycle (EPA 1975a). They were as stated above. Hearings in the ensuing months brought general but not unanimous approval of the approach taken as a first attempt to establish an ALARA approach to standards across the entire fuel cycle. There was, however, widespread criticism of the methods and validity of the data used to support the figures and the lack of involvement of a large number of informed agencies and individuals in the development of so broad a set of regulations. There were many (e.g., Parker 1976) who advocated a national effort to bring the "best collective judgement" to bear, to obtain a true consensus on evidence of health effects at low levels of radiation and "orderly prediction of when human data can be expected to yield positive results that can be tested against health effects postulates."

There were others (e.g., Evans 1976a; Taylor 1976; Liverman 1975, 1976; Mattson 1976) who took, in various forms and to various degrees, the view that current standards were functioning well, measurements in the environment at such low levels would be almost impossible to make and at best would be subject to large errors because they were at or near the limits of measurements, and that embracing the linear no-threshold formulation for dose-response was unacceptable for assessments of this kind.^(a)

Few of the objections involved specifics of pathway analysis, although many considered that it could not be done. We must pass by the details of many responses since they are beyond the purview of this chapter and bear more on the philosophy of standard-setting than on environmental transport.

It is obvious that there is room for legitimate differences of scientific opinion and judgment in this complex area. The broad fact remains that a fully national or preferably international consensus has never been aimed at, nor have suitable mechanisms been proposed to arrive at same.^(b) Thus, the guidance promulgated by EPA, in this area, stands as legally legitimate but seriously

(a) Note it was largely assessment that they were criticizing.

(b) The EPA may have taken the view that such a gathering could do nothing but agree to disagree. Also, the EPA was under pressure to produce radiation standards for the environment.

questioned on the grounds of the scientific basis for many of the derivations and the methodology and judgmental factors, including the wisdom of the fractionated approach.

The problems raised did not seem to be enough to force major changes, and the proposed limits went into effect under 40 CFR 190 as of the proposed dates. It is the NRC that has had the major burden of implementation. There have been a series of "Regulatory Guides" that incorporate or concentrate on implementation of 40 CFR 190 as well as 40 CFR 192.

6. Transuranium Elements in the General Environment

In 1976, the Nevada operations office of ERDA held a symposium at Gatlinburg, Tennessee, on the subject "Transuranics in Natural Environments." The report from this can be regarded as the beginning of a marked crescendo in interest in transuranic elements in the general environment. In 1977, EPA came out with yet another new document, which contained similar yet somewhat different proposals from those for the uranium fuel cycle. It was entitled *Proposed Guidance on Dose Limits for Persons Exposed to Transuranic Elements in the General Environment* (EPA 1977a) and was to cover all important pathways of the transuranic elements to humans. It suggested, as indicated earlier, limiting dose rates from exposure to transuranium elements in the general environment to 1 mrad/yr to the pulmonary lung or 3 mrad/yr to the bone; it stated that the recommendations be used only for guidance or possible remedial actions and not for limits on planned releases; and it suggested that implementation be on a site-specific basis. To facilitate implementation, they suggested that a soil contamination level of $0.2 \mu\text{Ci}/\text{m}^2$ for samples collected at the surface to a depth of 1 cm and below a stated particle size^(a) would establish "a reasonable screening level." A derived air concentration based on activity median aerodynamic diameter (AMAD) not exceeding $0.1 \mu\text{m}$ would be $1 \text{ fCi}/\text{m}^3$ for alpha-emitting transuranics. This constituted a screening level for the air.

There was considerable discussion of the risks associated with these levels. They were less than one chance in a million per year and less than ten chances per hundred thousand in a lifetime for development of cancer from continuous exposure at the stated dose rates. The fact that the guidance was aimed at the small fraction of the total population at greatest risk was also emphasized. There were illustrations of what the impact (or lack of it) would be at some of the sites known to be contaminated with transuranics (Rocky Flats, Mound Laboratory, NTS, and Trinity site). Finally, it was again emphasized that the guidance was not intended to supersede existing overall radiation protection guides.

It was proposed that agencies implementing the guidance be required to estimate dose rates to persons from measured air and/or soil concentration levels. It was stated that nearly all land outside the boundaries of existing contaminated sites in the United States is probably below the levels specified in the guidance, and little or no remedial action would be required.

This large volume, despite its caveats, brought another large volume of comments and criticisms. Many of them (e.g., ERDA, undated) were along the same lines as those in 1975–1976 for the uranium fuel cycle, e.g., the basic philosophy

(a) The report states a particle size "under 1 mm," but this author is not sure that that is what was meant.

used for standard setting, the linear no-threshold hypothesis, one area being selected out for attention, etc. Much must again be omitted since it does not bear directly on environmental considerations. Yet, it must be noted that the new numbers introduce very substantial burdens of implementation and enforcement—out of proportion in the opinion of many of those commenting—to the number of health effects prevented.

On the environmental side, there was heavy criticism of EPA's choice of the mass-loading approach to resuspension. This approach, as we saw earlier, involves the assumption that all airborne particles have their origin in the locally contaminated soil. As stated earlier, EPA introduced an "Area Correction Factor," which could be employed when the source area was small and perhaps did not contribute all of the measured activity in the air, but this was not considered sufficient.^(a)

In response to these and hundreds of other comments, the EPA produced a Response to Comments (EPA 1978b) and a revised text of the guidance. Basically the agency concluded that the comments did not raise substantive new issues and that the basic guidelines would remain. There were changes in detail and much rebuttal of the comments.

These proposals remain in a "draft" stage, although promulgated informally in the *Federal Register* (42 FR 60956, November 30, 1977).^(b)

7. Commentary

This review of standards applicable to the environment is cursory. It necessarily omits many pertinent arguments and discussions primarily because many of them have little to do with the environmental aspects of the design and justification for the standards. Some of the ideas can be found in other chapters. Even this cursory review, however, makes it clear that recent efforts have been fraught with controversy. The reasons are numerous.

1. Few of the recent statements give clear-cut derivations of the figures, especially the justification for judgments made.^(c) Those that do frequently have been criticized as lacking clear scientific grounds for acceptance.
2. The idea of separating off a particular radionuclide and a segment of the environment and applying a very low limit because it is only part of the total exposure has been difficult for many to swallow. General limits are frequently preferred.

(a) There was also an "enrichment factor" designed to account for nonuniform distribution of activity among particle sizes, but this was small and not considered very useful.

(b) Further action occurred in agency comments and supplementary information in an EPA Technical Report (520/4-78-010) whose availability was contained in a *Federal Register* notice in 1979 (FR 1979) and related documents (EPA 1978a,c). After a considerable period, "underground" guidance on transuranium elements in the general environment appeared in draft form as a *Federal Register* notice dated November 4, 1985 (EPA 1985). Three levels are proposed beginning at 1 mrad (10 μ Gy) per year to the pulmonary lung or 3 mrad (30 μ Gy) per year to the bone to a high, requiring monitoring and remedial action at doses not to exceed 500 mrem per year on an *intermittent basis*. Even this is still a draft so it appears that the pot still boils.

(c) This does not imply that all of the statements from other quarters relating to standards are as complete with derivations as would be needed to follow each item step-by-step.

3. The lack of gathering a true national consensus before important new regulations were proposed publicly was a cause of friction. Fortunately this has improved recently.
4. The need for new standards is doubted by many; it is insisted upon by many others.

The active participation of EPA considerably reduced the overt input to these subjects by the various laboratories in the internal emitter establishment, at least in the form of direct reports. They continued to participate, however, by individual or group participation, in the laborious hearing and commentary process. As we have seen; these have generated, for each proposed standard, volumes of arguments, statements of views, and much information on social and economic impact, etc., which played little part in the earlier standard-setting processes (chapter 16). A full description of these processes would require another book.

From the standpoint of this book, it is the difficulty of following the reasoning, not to mention the scientific basis in detail, that causes the most concern for many of the current and proposed standards for radionuclides in the environment. Since most of the levels producing problems are very low, there seems little doubt that the public health is being adequately protected. The dilemma is whether or not the cost is too high and unfair burdens are being placed upon one segment of the national enterprise. Since this is not a biomedical problem, no further comment is appropriate here.

We can conclude with a quotation from a paper given rather early in the development of these standards by Joyce P. Davis (Davis 1975). Dr. Davis combines a doctor of law degree with a bachelor's degree in physics and a master's degree in radiation biology, and has contributed some very informative and extremely well-balanced analyses of both the technical and legal problems of recent standard-setting activities. Her paper addressed the effect of the Federal Water Pollution Control Act (FWPCA) on NRC licensing jurisdiction and procedures. It included a capsule history that touched upon the National Environmental Policy Act of 1969 (NEPA) and the National Pollution Discharge Elimination System (NPDES). Her conclusions, including the prospects for a workable implementation of FWPCA are reproduced below:

The problems of cleaning up our nation's polluted waterways and of ensuring that all water bodies maintain a quality that permits their healthful use by man and other species on this earth are gigantic. Considerations of economics, ecology, and resource conservation must be carefully weighed in determining how resources of all types should be allocated to result in optimal benefit to the community.

The NPDES system establishes a framework for future action. One industry representative has referred to this framework as a skeleton needing to be clothed with muscle and flesh. Theoretically it creates a method whereby each source can contribute an equitable part to the maintenance of water quality, each source operator can know exactly what is expected of his facility, and enforcement can be facilitated. Whether this system will actually result in benefits to the natural and social environment depends not so much on the procedural aspects of the Act as on the substance of the effluent limitations actually set in the NPDES permits. The interpretation of the entire FWPCA will be reflected in the application of the permit system.

The effectiveness of the FWPCA could be substantially undermined by its overly rigid schedule of time deadlines; a lack of communication between industry and government and between government agencies; the possibility of duplication of efforts on, or even contention between, the EPA and other federal agencies or the federal and state levels of administration; the need for action in setting limitations

before adequate technical data are available; a lack of regard for the factors requiring individual rather than universally applicable limits; and a tendency to require "treatment for the sake of [t]reatment" or review for the sake of review. Any of these problems could become serious enough to severely hamper the efficacy of the permit program.

The EPA has recognized some of these difficulties and admits it is having "serious problems" implementing the FWPCA. The rigid time schedules are difficult to meet, and any slippage generally results in citizen suits to enforce them. The setting of "intelligent standards" for toxic pollutants within the time frame of the Act has been "virtually impossible," and the workload implications of the new requirements were not adequately anticipated. Some of the early regulations issued under the Act lack flexibility and may require modifications to make them workable. An EPA review and other studies have indicated that revision of the FWPCA effecting a relaxation of some of the deadlines and a change in the pace of spending for pollution control may be needed.

The opportunities presented by the new law are, however, correspondingly great. The NPDES provides a vehicle for defining, for every source, realistic, achievable, enforceable, and, above all, environmentally beneficial limits on effluent release. However, for these opportunities to be realized, all federal agencies, all levels of government, industry, and the scientific and technical communities must work together. There must be a free exchange of information and a willingness to evaluate in a single proceeding all aspects of the environment—natural, economic, and social—that are involved. If this can be done, the prospects for the FWPCA are excellent.

(Davis 1975)

V. Summary and Commentary

Some very sophisticated mixtures of engineering, aerosol physics, tracer chemistry, and biomedical science developed over the years to characterize the movement of radionuclides in the environment. Actually, it did not start with radioactivity problems. Industrial hygiene was well-developed in the pre-World-War-II years around the problems of air dispersion, air sampling, and aerosol characterization for nonradioactive dusts, fumes, and gases. But the large push in the atomic energy field contributed a leadership role. In recent years, modeling has occupied center stage. The field of environmental transport became, and is now, largely dependent on complex computer operations. In the eyes of some, the models have become living entities, transcending in importance the information they are supposed to correlate.

The first area to develop concerned airborne contamination. The industrial hygienists had provided a good start. In the early years, this area of our subject matter was almost a subsidiary of the field of industrial hygiene, including aerosol physics and meteorology. The primary focus was on the inhalation of any material, radioactive or nonradioactive, and its potential movement over geographically small areas. The general models developed in the 1930s for atmospheric diffusion; the role of turbulence, of particle size and composition, wind velocity and the like were applied in the 1940s et seq. to releases of radioactivity. Special attention was focused on equations developed to account for stack height and the presence or absence of obstructions such as buildings.

All of this later tied in with the larger-scale patterns of air movement found from the behavior of local and global fallout from nuclear weapons tests.

During the years of World War II, needs to know the movement of radionuclides in media other than air gradually developed. Terrestrial transport demanded considerable attention. In contrast to atmospheric transport, a major role of biota, especially vegetation, was found in the case of terrestrial transport. Naturally, the chemistry of the involved soil was a major consideration. Many of the more important variables turned out to be in the properties of soil and in soil-plant interactions.

Transport in surface water was, of course, an obvious need, particularly for systems such as the Columbia River, Clinch River, and, later, the Savannah River. Transport phenomena in rivers were found to be quite different from lakes, and estuaries different from the ocean. Biological systems were found to play important roles in surface water transport too. Biota move appreciable quantities of radionuclides in surface water systems. Models for freshwater food webs, compartments of a lake ecological system, and transformations within a body of water are shown.

The practice of disposing of radioactive wastes in pits and trenches focused attention, like the similar practice of dumping chemical wastes, on transport by ground water. Because of the exquisite sensitivity of radiation measuring instruments, minute leakages into ground water could be measured. Of special interest for radiation hazard evaluation is the very slow movement of ground water, except where fissures or cracks produce an underground stream. Biota play only a minor role in the transport of radionuclides in underground water.

An important endpoint of all of the environmental transport modeling was dietary pathways and usage. This entailed detailed research on dietary usage factors of numerous foodstuffs by infant, child, teen, and adult. To simplify the analysis of pathways, the International Commission on Radiological Protection suggested determining a "critical pathway" for each of various important circumstances. This was defined, of course, as the pathway that brought the most radionuclides to the ultimate recipient, humans. Along with this, the idea of a "critical population" was developed, this being that segment of the population, sometimes very small, that was predicted to have the largest intake from the critical pathway. These were, of course, nuclide-specific and system-specific. The idea provided a very useful simplification that was much needed in the days before rapid and comprehensive computer analyses, which can handle numerous pathways and populations almost simultaneously. In the case of mixtures, a third simplification, the "critical nuclide," was added. Examples are given of typical analyses based on these postulates.

As part of the growing volume of research information and the realization of the presence of concentration factors, as well as discrimination factors, it became obvious that radionuclides were recycled in the environment to a considerable extent. There were few "once-through" systems. The transport models had to take account of recycling,^(a) and anyone generating standards needed to be cognizant of these phenomena.

While recycling received much emphasis in aquatic and terrestrial systems, it also took a part in air transport. Hence, the fact that surface winds could

(a) Sometimes referred to as "reconcentration."

transport already deposited radioactivity to new sites by the process of "resuspension" was appreciated and utilized in models, particularly for arid environments. A single factor for resuspension was used in many analyses, even though the resuspension factor has a very large range.

Although many laboratories were involved in modeling the transport of radionuclides in the environment, the Hanford, Lawrence Livermore, and Oak Ridge groups have been especially involved. The chapter provides a summary of some of these efforts, plus the fact that much modeling has been done for preparation of environmental impact statements for nuclear facilities.

Isotopes of strontium, cesium, iodine, and of plutonium and the transplutronics have received sufficient attention with regard to their environmental transport to warrant specific summaries in this chapter. The work with strontium indicated that it was much less strongly complexed with the components of soil than many other important radionuclides. As a result, it remains quite mobile.

The work with cesium, among other things, brought out vividly how the characteristics of the ecosystem could influence environmental transfer. In the Arctic, a very short food chain exists: source-lichen-reindeer or caribou-human. As a result, cesium concentrations, arising from fallout, in residents of the far North were considerably higher than those in lower latitudes. Also, it was apparent that discrimination against cesium in the environment versus its homologue, potassium, was much less well developed than that for strontium over calcium.

Iodine transfer was, of course, of key importance in fallout from weapons tests. It is also among the more important potential effluents from nuclear installations. It was iodine transfer from the environment that first focused attention on the key role of food chains. Besides the experience with iodine in fallout, described in chapter 12, there were specific field tests. Among these were the Controlled Environmental Radioactive Tests that took place at Idaho Falls. These led to derivation of mathematical models for transfer to milk and prediction of the dose to humans. They, along with data from other sources, led to a drastic reduction in the allowable limit for iodine discharges from light-water-cooled reactors.

Plutonium and the transplutronics move relatively slowly in the environment, except when airborne. Because of their long half-life and damaging alpha-particle emission, these elements have received attention perhaps beyond their current biomedical significance as environmental hazards.

The chapter closes with a discussion of dose assessment for populations from environmental sources and for portions of the environment. This includes a fairly detailed review of ideas and methods for assessing radiation dose to populations and illustrations of the calculations made. Also, the development and use of the resuspension factors are reviewed because of the important part they have played in predicting population dose. Finally, environmental and population standards for drinking water, surface contamination, soil contamination, the effluents from light-water-cooled reactors, the uranium fuel cycle, and transuranics are reviewed briefly. Environmental transfer factors play an important role in the generation of all of these standards.

Important and sophisticated treatises are now available on the movement of radionuclides in the environment. Obviously, there are many gaps where "default" numbers must be used instead of actual data for the specific situation. However, the effort, begun in the years of World War II as described in chapter 11, has come far and can stand as a model for more general analyses of environmental contamination.

L.-E. Larsson	
Discussion	373
Genetically significant dose from the use of radiopharmaceuticals (IAEA-SM-184/3)	377
H. D. Roedler, A. Kaul, G. Hinz, W. Pietzsch, F. E. Stieve	
Genetically significant dose to the population in India from X-ray diagnostic procedures (IAEA-SM-184/33)	395
S. J. Supe, S. M. Rao, S. G. Sawant, G. Janakiraman, A. Ganesh	
Discussion	410
A practical method of assessing radiation doses to the population: The use of reference levels and some results of their application to Italian sites (IAEA-SM-184/38)	413
G. Boeri, Carla Brofferio	
The problem of the assessment of the radiological impact on populations from radioactive discharges: Some consideration on the concept of global risk (IAEA-SM-184/39)	423
G. Boeri, F. Breuer, Carla Brofferio	
Discussion	426
Environmental characteristics of the Danube River system and the problems of radiological safety standards (IAEA-SM-184/43)	427
T. Tasovac, R. Radosavljević, M. Zarić	
Discussion	432

POTENTIAL HARM AND ECOLOGICAL ASPECTS AND CONTROL

POTENTIAL HARM TO POPULATIONS FROM EXPOSURES (Session VII)

Considerations in assessing the potential harm to populations exposed to low levels of plutonium in air (IAEA-SM-184/14)	435
W. J. Bair	
Discussion	448
Assessment of potential health consequences of transuranium elements (IAEA-SM-184/16)	451
N. F. Barr	
Discussion	461
Health effects of alternative means of electrical generation (IAEA-SM-184/18)	463
K. A. Hub, R. A. Schlenker	
Discussion	482

TRANSFER OF RADIONUCLIDES TO MAN THROUGH
ENVIRONMENTAL PATHWAYS (Session VII continued and Session VIII)

Transfer of radionuclides to man through environmental pathways (IAEA-SM-184/105; Invited review paper)	485
N. T. Mitchell	
Discussion	499
Transfer of ^{137}Cs and ^{90}Sr from the environment to the Japanese population via marine organisms (IAEA-SM-184/7)	501
T. Ueda, Y. Suzuki, R. Nakamura	
Evaluation of the resuspension pathway toward protective guidelines for soil contamination with radioactivity (IAEA-SM-184/13)	513
L. R. Anspaugh, J. H. Shinn, D. W. Wilson	
Discussion	523

Incidence des reconcentrations radioécologiques sur la valeur de la concentration maximale admissible des eaux de rivière (IAEA-SM-184/22)	525
R. Schaeffer	
Discussion	537
Sorption-desorption of radioactive caesium, strontium and cerium on earth components (IAEA-SM-184/41)	539
M. Pirš	
Discussion	550
CONTROL OF POPULATION DOSES (Session IX)	
The estimation of radiation dose rates to fish in contaminated aquatic environments, and the assessment of the possible consequences (IAEA-SM-184/11)	555
D. S. Woodhead	
Miscellaneous sources of ionizing radiations in the United Kingdom: The basis of safety assessments and the calculation of population dose (IAEA-SM-184/12)	577
A. D. Wrixon, G. A. M. Webb	
Discussion	590
Radiation dose to population (crews and passengers) resulting from the transportation of radioactive material by passenger aircraft in the United States of America (IAEA-SM-184/15)	595
R. F. Barker, D. R. Hopkins, A. N. Tse	
Discussion	610
Etude d'un écosystème aquatique naturel contaminé in situ par des effluents liquides tritiés, en vue de l'évaluation de la sensibilité des paramètres des niveaux d'exposition du public (IAEA-SM-184/27)	613
R. Bittel, R. Kirchmann, G. van Gelder-Bonnijns, G. Koch	
Discussion	621
Rapport général: Synthèse de la situation actuelle et remarques finales (IAEA-SM-184/106)	623
H. Jammet	
Discussion	628
Chairmen of Sessions and Secretariat	631
List of Participants	633
Author Index	645

Capsule Chronology^(a)

- 1925 International Congress of Radiology organized.
- 1928 Organization and first meeting of International Committee on X-ray and Radium Protection (predecessor of ICRP).^(b)
 Organization of U.S. Advisory Committee on X-ray and Radium Protection (predecessor of NCRP). First meeting in 1929.
- 1941 Formulation of standards for radium and radon (NBS; Evans and Goodman). Based directly on data concerning effects in humans for radium, and atmosphere in mines for radon.
- 1942–1945 Several standards developed on more or less individual basis for the MED operations (see also earlier chapters).
- 1944 Air limits for plutonium derived at Met Lab.
 Exposure standard for natural uranium set arbitrarily by analogy to lead.
- 1945 Landmark paper by Cantril and Parker on tolerance dose.
 Morgan circulates first comprehensive calculations of maximum permissible body contents and concentrations in air and water for many radionuclides in a Met Lab Report called "Tolerance Concentrations."
- 1945–1946 Inhalation experiments at Rochester made basis for revision of standard for uranium. Different levels recommended for soluble versus insoluble salts.
- 1945 et seq. Standards developed for plutonium on basis of animal toxicity data. Earliest attempts are on basis of half-life relative to radium, but animal work proves this to be incorrect.
- 1946 Reorganization of U.S. Advisory Committee. Renamed National Committee on Radiation Protection and operates out of the Bureau of Standards. Has two subcommittees on radionuclide problems.
- 1947 Publication of Morgan's compendium on tolerance concentrations of radioactive substances. The computational approach.
 Parker describes standard setting and operational limits used in MED operations and important principles.
- 1949 First Tri-Partite Conference on Internal Dosimetry (Chalk River, Ontario). Accumulated experience of the war years utilized.
- 1950 Need for better relative toxicity data for bone seekers generates the Utah project and expansion of Argonne work.
 Second Tri-Partite Conference on Internal Dosimetry (Buckland House, Harwell, U.K.).
- 1950s AEC develops regulations for individual radionuclides under occupational exposure conditions.

(a) Many of the events pertinent to the subjects of this chapter have already been cited and will not be repeated here, unless of special importance.

(b) For abbreviations and acronyms, see Appendix D.

- 1951 First organizational recommendations since 1941 for permissible levels of radionuclides, primarily from NCRP.
- 1953 Third Tri-Partite Conference on Internal Dosimetry (Arden House, Harriman, New York).
- 1954 Indications appear that tissue burdens of uranium in man are lower than predicted by models (Eisenbud and Quigley, AEC).
- 1955 Formulation of standards for single exposures (Morgan, Snyder, Ford).
United Nations Scientific Committee (UNSCEAR) organized to gather information, much of it pertinent to standard setting.
- 1956 Indications that uranium may be less toxic to humans than animal experiments predicted (Eisenbud).
Early reports of strontium metabolism in man (Comar, Laszlo, Spencer).
- 1957 American Council of Governmental Industrial Hygienists suggests a single value for air concentration of both soluble and insoluble natural uranium.
- 1958 Bureau of Radiological Health organized within U.S. Public Health Service.
- 1959 Report of Committees 2 of NCRP and ICRP on occupational limits for exposure to radionuclides. Utilizes dual system; uses effects directly for radium and bases other bone seekers on it; uses the computational approach for all others using external radiation effects as basis.
Federal Radiation Council (FRC) formed to advise the U.S. President about radiation matters, especially standards. Series of reports issued. See below and chapters 3, 12, and 15.
- 1960 First series of BEAR reports issued by NAS-NRC. Does not address standards directly, but contains much pertinent information.
- 1960s Large effort at Oak Ridge on trace elements in human tissue (Tipton).
Beginning of population exposure standards (chapter 15).
AEC develops elaborate code of Federal Regulations for radionuclide exposure (10 CFR 20 et seq.). Patterned after 1959 ICRP/NCRP reports, but adds population exposure limits by use of a scaling factor.
- 1960-1961 First two reports from FRC on basic radiation protection guides. Introduces formally the concept of balancing risks and benefits.
- 1962 FRC Report No. 3 on health implications of fallout.
One of several Congressional hearings on fallout starts. Several bear on standards and their validity (see earlier chapter listings).
- 1963 FRC Report No. 4 on estimates and evaluation of fallout in the United States through 1962.
A second Congressional hearing including Radiation Standards and Fallout.
- 1964 FRC Report No. 5—more on development of standards.
FRC Report No. 6—revised standards for fallout.

- 1964** NCRP becomes a Congressional Charter Organization and is named National Council on Radiation Protection and Measurements.
- 1965** FRC Report No. 7—Protective Action Guides for ^{89}Sr , ^{90}Sr , ^{137}Cs .
- 1966** Publication of new lung model from ICRP Task Group on Lung Dynamics.
Publication of model for dosimetry of gastrointestinal tract by Eve and Dolphin and Eve, United Kingdom.
- 1968** ICRP Report on handling single intakes. Time integral of dose utilized.
U.S. Transuranium Registry organized. Data especially pertinent to validation of standards.
- Late 1960s** Congress institutes environmental impact statement as result of Calder Hall case. A new phase begins in population dose standards and protection.
- 1970** EPA takes over standard-setting functions for the environment. Later to be shared with Nuclear Regulatory Commission.
- 1970s** NAS-NRC BEIR committee begins work on evaluation of low-level radiation exposure.
National Environmental Protection Act changes status of all environmental protection standards.
- 1971** Large LLL report on elemental concentrations in human organs (Anspaugh et al.).
Review of data from the eighteen patients injected with plutonium (chapter 7) validates most of the original metabolic data (Durbin at Berkeley).
Lauriston Taylor's short book on history of standard setting published.
- 1972** The ICRP bone dosimetry model (Marshall model) is published.
First report of mortality experience in uranium workers (Scott et al. at Oak Ridge).
- 1973** Hursh and Spoor review data for uranium in man.
Remeasurements of plutonium patients (Rundo, ANL).
Complete review of twenty-five Los Alamos workers from MED days (Hempelmann, Richmond, Voelz).
Cancer statistics among uranium workers reviewed (Archer et al., Salt Lake City).
- Mid-1970s** AEC disbanded. Regulatory and standards-setting functions transferred to new Nuclear Regulatory Commission for application to licensees. Agencies still have some jurisdiction over own operations. EPA assumes jurisdiction over general environmental aspects.
- 1975** ICRP Report on Reference Man published. Result of years of effort in many laboratories. Used for nearly all dose calculations and assessments.
First reports on epidemiology of uranium indicate standards have been adequate but need more follow-up.
Hursh's review of origin and basis of standards for uranium.

- 1975 Code of Federal Regulations modified to account for role of food chain in transport of radionuclides. Appendix I of 10 CFR 50 mandates large reduction of limits for effluents from light-water-cooled reactors. (Prepared May 5, 1975, effective June 4, 1975.)
- 1977 Los Alamos resident survey.
- 1977-1979 Mancuso studies reported. Generates considerable polemic.
- 1978 ICRP Publication-30 approved on Limits for Intakes of Radionuclides by Workers. Discards direct approach for bone seekers and concentrates on computational approach for all radionuclides. Followed by several supplements that give details for hundreds of nuclides utilizing computerized retrieval and use of metabolic data accumulated over several decades. Published in 1979.

U.S. Uranium Registry established. Very important to future validation of standards.
- 1979 A further complete review of the Los Alamos MED workers (Voelz). Results appear to validate even the old high standards, but group too small for epidemiologic significance.

Lauriston Taylor's large book on history of ICRP and NCRP published.
- 1980 Reports on health of thorium factory workers do not validate the high toxicity assigned to radiothorium by the computational approach.
- 1981 Evans's review of development of radium standards.

Parker's review of wartime operations and standards, especially vis-à-vis plutonium.

Stannard reviews uses of laboratory research in setting standards for exposure to radionuclides.

Taylor reviews standards.

Information on americium case from Richland helps with validation process (U.S. Transuranium Registry).

Reports of late excretion rates of plutonium following acquisition of known amounts (Rundo, ANL).

Further data on mortality of Oak Ridge uranium workers (Polednak and Frome).
- 1982 Report of tissue contents of plutonium from 180 autopsy cases dying from natural causes (McInroy, Los Alamos).
- 1983 Formal report on over 19,000 Tennessee Eastman employees. Some potential excess risks found, but not proven yet (Cookfair et al.).

Chapter 16

Internal Emitter Research and Standard Setting: Validation In Man

Overview

In this chapter, we show how the research findings reviewed in this book have been and are being applied to the process of limiting intakes of radionuclides so that the amounts deposited and retained in the body are kept within acceptable limits. We also consider briefly some of the applications of the research to problems of environmental limits discussed in chapter 15.

The motivation for the early biomedical research work with radioactive materials was primarily (1) to establish the behavior and biological effects of deposited radionuclides and (2) to use the information to develop standards. There is no doubt that the enviable overall occupational health record of the atomic energy industry could not have been achieved without the products of these research efforts. Conversely, where the research and its application were neglected in the early days, the health record has not been so enviable (e.g., the uranium miners).

Before considering how the results were used, the chapter digresses for a short review of the organizations and some of the key individuals involved in the process. This is by no means a history of radiation protection philosophy or activities. There is enough detail, however, to aid in comprehension of the systems to which the research data were applied, including some of the basic formulations. Details are reserved for chapter 20.

We then examine in some depth those standards that can be said to have been derived directly from experience and experiment. This is termed "Direct Derivation of Standards." The elements discussed are radium, radon, uranium, plutonium, ^{224}Ra , and ^{232}Th . There is also a short discussion of the approach of the Federal Radiation Council, since it utilized primarily direct derivations.

Obviously, the number of elements with sufficient information for direct derivation of standards is relatively small. The others, including the hundreds of new radionuclides produced in nuclear fission, required an indirect approach. We have termed this "The Computational Approach." It involved the design of a general system that allowed computation of maximum permissible body burdens and maximum allowable concentrations in air and water by use of the

metabolic information on behavior of the substances of interest. The two-pronged approach, one for elements that localize in bone, the other for elements that do not localize in bone, is described. The special features of the computational system, along with later modifications for single and population exposures, are touched upon lightly, as is the important work on determining concentrations of stable elements.

The research information on radionuclides has contributed most heavily to the establishment of retention kinetics, general metabolic models, and special models such as those for lung and gastrointestinal tract. The latter two, along with the construction of Reference Man (Standard Man), required much use of basic physiological, biochemical, and anatomical knowledge as well, but the slant was always toward development of standards. This is reviewed in two sections on modeling.

The last major section of the chapter considers work bearing on the validation of the standards already developed, largely by work involving humans. This embraces the validation of both the metabolic models and the basic standards themselves by means of autopsy programs and a growing cadre of epidemiologic projects. Included are the patients and workers exposed to plutonium and the development of the U.S. Transuranium Registry; validation of models and limits for uranium, including the relatively new U.S. Uranium Registry, and the quite new epidemiologic work at Oak Ridge on former Manhattan Engineer District uranium workers; and the fission products, especially strontium and iodine. It is concluded that by and large the models and limits have been and are being satisfactorily validated with some exceptions, the most notable of which is uranium, where both the amounts deposited and toxic effects in human kidney are considerably below predictions. Another exception concerns the environmental behavior of certain nuclides such as iodine where the amounts permitted to enter the environment have had to be lowered very substantially. Plausible explanations are given for each major deviation from expected behavior.

In the final section, labeled "Epilogue," we see that scientific information *per se* is now having less effect on standard setting, both for radionuclides and for other potential hazards than it did in the primary period of this book. This is because the proposed levels are getting so low that it appears almost impossible to design scientific experiments that can prove or disprove a given hypothesis for a dose-effect relationship. The scientific data input to metabolic models and to environmental models continues of major importance, however. Finally, the chapter emphasizes that new efforts should be directed toward the estimation of risk from deposited radionuclides.

I. Introduction

This chapter represents to some degree a synthesis of much that we have reviewed to this point. The purposes of the various lines of research have been multiple. In addition to the usual scientific motivation to obtain new knowledge and to test hypotheses, anticipated applications to the setting and validation of occupational and population limits of exposure and intake of radionuclides have been of primary importance. Only applications to medicine, to the problems of handling radioactive materials, and the behavior of radionuclides in the environment have approached in importance the practical objective of standard

setting. Indeed, parts of the earlier programs, especially in the days of the Manhattan Engineer District (MED), were almost totally oriented toward obtaining information that could be utilized *almost immediately* for establishing maximum permissible intakes, body and organ burdens (Friedell 1983).

A corollary to the generation of new data that could be used in standard setting has been the need to examine in retrospect *in humans* the validity of the limits imposed. Since the limits are all at levels where overt biomedical effects are extremely unlikely, this validation process has applied more to checking out in man the many metabolic parameters applied than to incidence of effects, with a few exceptions. However, incidence of any and all possible biomedical effects has been diligently explored. In the case of ^{226}Ra , ^{224}Ra , and ^{222}Rn and its progeny, where the intakes preceded or ignored the developing standards, there has been a continuous opportunity to accomplish direct validation in man in terms of effects. For many other radionuclides, the search for effects has had to become retrospective epidemiology.

The chapter will perforce consider some of the organizations that utilized the research data and the manner in which they focused the results of research onto the standard-setting process. We will need to consider some of the divisions of responsibility developed over the years. However, we will in no sense attempt a formal history of the people and organizations engaged in radiation protection or its philosophy. These have already been expounded in depth by professionals who have devoted their lives to the process. Convenient among these for our purposes are Lauriston Taylor's reviews at the first Atoms for Peace Conference (Taylor 1956a,b), his short book (Taylor 1971), his historical review at the silver anniversary meeting of the Health Physics Society (Taylor 1981), and his monumental treatise drawing together nearly every documented activity of the International Commission on Radiological Protection (ICRP), the U.S. National Council on Radiation Protection and Measurements (NCRP) and their predecessors, and correlated activities in the radiological community (Taylor 1979).

Despite its size, the large Taylor compendium purposely leaves blank the section intended to deal with the 1941 to 1946 years of the atomic energy project in the United States, i.e., the MED. He states his hope that H. M. Parker, "who was involved in the radiation safety project^(a) from the outset, and who brought to the project many years of experience in the medical physics field, will someday fill in this most important gap" (Taylor 1979, p. 6-001). Fortunately, although it was necessarily somewhat abbreviated, Parker did give the essence of the development and operation of the Plutonium Project Protection Programs at the Health Physics Twenty-Fifth Anniversary Meeting (Parker 1981).^(b) This updated an MDDC report declassified in 1947 (Parker 1947 and 1980). The report is comprehensive and goes well beyond Manhattan Project experience. It involves instrumentation and procedures in depth as well as organizational aspects. It is exceeded in depth and usefulness only by what must now be regarded as a true classic of the era, the paper on the "tolerance dose" prepared

(a) At Clinton Laboratories and the Metallurgical Laboratory first, but primarily at Hanford.

(b) Taylor's original wish can never be completely fulfilled since Mr. Parker is no longer with us.

by Cantril^(a) and Parker in 1945 while the operations were still at the Clinton Laboratories at Oak Ridge (Cantril and Parker 1945).

Further details are contained in another summary from the 1940s prepared by Karl Z. Morgan and reproduced in the Health Physics Society's Twenty-Fifth Anniversary volume (Morgan 1946 and 1980).^(b)

A recent compendium of special usefulness because of the variety of subjects included is the result of a special conference called "Health Physics: A Backward Glance" (Kathren and Ziemer 1980), developed at a meeting of the Hoosier chapter of the Health Physics Society. The first paper in this volume gives a review of the first fifty years of radiation protection.

For a smorgasbord of essentially every aspect of radiation protection, the several hearings of the Congress of the United States held under the auspices of the Joint Committee on Atomic Energy are especially useful. One two-volume set with over two thousand pages is devoted to broad discussions of radiation protection criteria (U.S. Congress 1960a,b). The witnesses cover every conceivable segment of the field and most organizations or jurisdictions with a legitimate interest in the subject. These volumes are, of course, unedited and do not take up the polemics which arose in later years. Nevertheless, the hearings provide a comprehensive review of both historical developments and contemporary problems.^(c) With these reviews and the cited literature therein, a reasonably comprehensive overview can be gleaned.^(d) Our task now is to pinpoint how the research operations nurtured these activities as they apply to standards for radionuclides. However, we must first examine briefly the people and organizations involved.

II. Who's Who

Even though we are consciously eschewing any attempt at a comprehensive history of radiation protection, it is important to identify the organizations and some of the principal people we will be relating to in this chapter. Those organizations that are known well and whose origins and history are readily available will be considered relatively briefly. Some others whose characteristics and

(a) Sidney Cantril was a close colleague of H. M. Parker beginning during their days at Swedish Hospital in Seattle.

(b) Obviously, the reports just cited do not pertain organizationally to other than the MED and its contractors since this was the milieu in which the developments took place. The Taylor syntheses on the other hand concern largely ICRP, NCRP, the National Bureau of Standards, and organized radiology and radiological physics.

(c) There were, in addition, hearings on specific problems such as the uranium miners (see later sections of this chapter).

(d) Whole sessions at numerous symposia and congresses have been devoted to overviews of radiation protection practices around the world. They can be found easily in the cited literature in this book. Also, anyone interested in a strictly chronological review will find the volume prepared by Robert I. Bell at Auburn University extremely useful (Bell 1977). This is encyclopedic with short notes on events from 1661 to 1977. Obviously, the first part is early physics and chemistry, that gradually flows into radiobiology and then into development of protection standards. Having struggled to find when certain events took place, certain procedures evolved, certain organizations were founded, etc., this author can readily appreciate the magnitude of the task, which Bell, with help from his family and his university, undertook. Since the volume is privately printed, the author's full address is given in the bibliography.

contributions need special attention to assure their recognition by posterity are taken up in greater detail.

We will arbitrarily divide the groups into those whose primary function has been the formulation of *recommendations* and those whose function was (and is) the establishment of *regulations* with the force of law. Sometimes the recommendations were translated almost verbatim into regulations, but that was the choice of the regulators and in no way negates the basic difference in intent.

A. The Advisors

1. Early Organizations

The International Committee on X-ray and Radium Protection. The radiological societies of a number of countries organized an International Congress of Radiology in 1925 (Taylor 1979). They realized that radiation protection would assume greater importance as radiology grew. Several member societies prepared proposals for some sort of international committee on radiation protection. This came to fruition in 1928 with the organization and first meeting of what was called the International Committee on X-ray and Radium Protection. This was part of the Second International Congress of Radiology held in 1928. The organization continued as an affiliate of the International Congress organization.

Official recommendations were issued about every three years except for the period 1938 to 1949. Most of these concerned external radiation sources. Except for a small secretariat, all those serving on the committee were volunteers.

The U.S. Advisory Committee on X-ray and Radium Protection. As described by Taylor (1979), a need appeared for individual countries to “present a more consolidated position with regard to national needs” and in preparation for international conferences. Indeed, there had been some embarrassing times when the American members were in wide disagreement. In September and December of 1928, three U.S. radiological societies, the American Medical Association and several x-ray equipment manufacturers agreed to the establishment of a protection committee. This was called the U.S. Advisory Committee on X-ray and Radium Protection. It got started in 1929. L. S. Taylor was elected chairman, partly because he was the American representative to the international committee, and partly because he was a “natural” for the job. Since his home base was the National Bureau of Standards (NBS), the Bureau agreed to commit some resources to its management. Like many temporary arrangements, it turned out that the Bureau was host for over two decades. Most of the earlier reports were issued as NBS Handbooks. Again, its early concerns involved mostly external radiation sources. The committee did not meet between the end of 1941 and 1946. Its members also served on a voluntary basis.

2. NCRP and ICRP in the Early Postwar Years

In 1946, the American Advisory Committee assembled to revise NBS Handbook 20 on “X-ray Protection.” Instead, they decided that a reorganization was needed. The membership needed to be broadened to include all U.S. organizations interested in radiation protection. (These are enumerated by Taylor, 1979, p. 7-005.) At this time, the name was changed to National Committee on

Radiation Protection. Subcommittees were added to the structure; this including a subcommittee (Subcommittee-2) on Permissible Internal Dose chaired by K. Z. Morgan from Oak Ridge. The only other subcommittee concerned primarily with radioisotopes was Subcommittee-6, which was chaired by H. M. Parker from Hanford. It considered the handling and disposal of radioactive isotopes, including the fission products. The first meeting of Subcommittee-2 occurred in September 1947.

In all of these years, neither NCRP nor the Bureau of Standards had any statutory responsibility for radiation protection.

The International Commission on Radiological Protection (replacement for International Committee) got going somewhat later after the end of the war. There was preliminary work in several countries, particularly in the United Kingdom. The first postwar meeting occurred in 1950 in conjunction with the Sixth International Congress of Radiology. It was only one day long. Nevertheless, some recommendations were posed, none of them concerning radionuclides, except to indicate that values for "internal radiation" would appear later. Subcommittees were designated, essentially identical in subject matter to those of NCRP. The first Tri-Partite Conference (section 4) had already been under way, and there was some mixing of ICRP and Tri-Partite members, especially for the second Tri-Partite meeting, which was held in England. By this time, internal dose was a lively topic in ICRP, but it was NCRP that had led the way initially, along with the Tri-Partite conferences.

3. NCRP and ICRP in Later Decades

In 1964, the NCRP became a U.S. Congressional Charter Organization under Public Law 88-376. Its name was changed to *National Council on Radiation Protection and Measurements*. This came about because of the increasing awkwardness of having it "sponsored," even informally, by NBS while it was not a governmental organization. Also, development of the Federal Radiation Council (FRC) (see section 5) had brought about many problems of interrelationships between the governmental and nongovernmental modes of operation. Under a Congressional charter, the NCRP could be an independent body, free to cooperate at will with ICRP, FRC, ICRU,^(a) et al. The association with the NBS and publication of the reports as NBS Handbooks ceased, although it was an entirely amicable parting.^(b) The various subcommittees of the executive committee became committees. The functions of the former executive committee were assumed by a board of directors. The internal dose problems were concentrated in Committee-2. Many new committees were formed and the parallelism with ICRP began to fade. However, Lauriston S. Taylor continued as president, and, except for a small secretariat, the members served, as before, on a voluntary basis.

In 1968, Committee-2, which had been chaired by K. Z. Morgan from the very beginning, was disbanded. Its functions were replaced by several internal emitter

(a) International Commission on Radiation Units and Measurements.

(b) An interesting side light was the renumbering of all of the issued NBS Handbooks as NCRP reports. Do not be confused by the double numbering seen in some of the references or the NBS numbering on the early ones. Only in retrospect did the earlier reports become "NCRP" reports. This led John Hursh in his excellent review of Report No. 39 (Hursh 1972) to wonder if "the NCRP child was reluctant to acknowledge its NBS father."

committees. There were flaws in that organization—a case of a system where the best of intentions just did not work even though several reports on specific elements were prepared. In 1977, a single committee was again established for internal emitter standards, that had some of the functions of a steering committee.^(a) Much of the work was parceled out to task groups.

There were, and are, other committees and task groups working on aspects of radionuclide behavior, e.g., environmental aspects, waste disposal. A history of some of this work can be seen in the report of Scientific Committee 57 (NCRP 1985a). Rosters of membership are in NCRP annual reports and the compendium by L. S. Taylor (1979).

In the following sections, we will see much of the work of the original Committee-2, since it predominated the period we must consider most closely. However, the results of other committee activities will be mentioned as appropriate.

During these decades, the ICRP changed less than did the NCRP. It remained relatively compact, with a main commission and four committees. Committee-2 continued to be the one chiefly cognizant of internal emitter standards. Committee-4 became involved with practical evaluations of radionuclide contamination, including the environment as well as the work place. There were official observers to ICRP from several international organizations and a number of special task groups were appointed, many of them under Committee-2. We will discuss their work in connection with specific matters. The secretariat was small originally, but has grown. Currently (1985), it is headed by F. D. Sowby at Sutton, Surrey, United Kingdom. The chairman changes every few years. Morgan continued to chair ICRP Committee-2 until J. Vennart succeeded him in 1973.

One major difference in practices between NCRP and ICRP is that the main commission of ICRP is the final decision maker. In NCRP, matters of *basic* radiation protection criteria must go through Committee-1, and any needs for real arbitration go to the board of directors. However, the primary hurdle is that every report must have approval, or at least not be disapproved, by each member of the entire seventy-five member council.^(b) As a result, the NCRP has seldom had to retract a recommendation. On the other hand, the process is frequently a painfully slow one. It has been definitely slow for the internal emitter work. However, recently the NCRP has produced several reports concerning radionuclides that are cited in other chapters and recently a general document (NCRP 1985a) responding for U.S. practices to the concepts contained in ICRP reports 26 and 30 (ICRP 1977, 1979).

4. The Tri-Partite Conferences on Internal Dosimetry

Very soon after the end of World War II, scientists involved with the biomedical problems of radioisotopes felt the need to establish standards for radionuclides on a much more general basis than before. There were also many aspects of external radiation standards that needed work. Representatives of the three countries that had worked most closely together on radionuclides during the war (Canada, the United Kingdom, and the United States) met together, hence the name “Tri-Partite Conferences.” One reason for this selection of

(a) This is NCRP Scientific Committee 57. It is chaired by the author of this book. There are about thirty scientists involved in the committee and its several task groups.

(b) Occasionally, a negative vote has been allowed to stand, but this is unusual.

membership was the perceived need to work with material that had not yet been declassified. These three groups already had liaison established.

There were three conferences:

Chalk River, Ontario, September 29-30, 1949

Buckland House, near AERE, Harwell, United Kingdom, August 4, 5, 6, 1950

Arden House, Harriman, New York, March 30, 31, April 1, 1953.

There was also an informal meeting or two built around other activities. The Chalk River Conference was extraordinary for its breadth and depth of coverage. The attendees had done their homework well. Those participating were:

United Kingdom

Mr. A. C. Chamberlain
Dr. E. F. Edson
Prof. J. S. Mitchell
Dr. G. J. Neary (secretary)

Canada

Dr. A. O. Braaten
Dr. H. Carmichael
Dr. A. J. Cipriani
Dr. G. H. Guest
Dr. G. C. Laurence
Dr. W. B. Lewis
Mr. G. E. McMurtrie (secretary)
Dr. E. Renton

United States

Dr. Austin Brues
Dr. G. O. Failla
Dr. J. G. Hamilton
Dr. L. Hempelmann
Dr. D. E. Hoffman (secretary)
Dr. Wright Langham (secretary)
Dr. K. Z. Morgan
Mr. H. M. Parker
Dr. L. S. Taylor
Dr. Shields Warren
Dr. B. S. Wolf

The names of most of the U.S. delegation members are already familiar from past chapters of this book.

The second conference, at Buckland House near Faringdon, Berks, had a much smaller U.S. representation and a large U.K. representation. They were:

United States

Prof. Robley D. Evans (part-time)
Dr. R. D. Marinelli
Dr. Lauriston Taylor
Dr. Shields Warren

Canada

Dr. A. Cipriani
Dr. G. C. Laurence

United Kingdom

Mr. W. T. Binks (part-time)
Mr. A. C. Chamberlain
Sir John Cockcroft
Dr. E. F. Edson
Dr. A. Glücksmann (part-time)
Dr. L. H. Gray (part-time)
Dr. J. F. Loutit
Dr. W. G. Marley
Prof. W. V. Mayneord (part-time)
Dr. G. J. Neary
Prof. F. W. Spiers (part-time)

The third meeting, at Arden House in Harriman, New York, was, of course, well populated with U.S. delegates. The attendees were:

United Kingdom

Mr. W. Binks
Dr. J. F. Loutit
Dr. W. G. Marley
Prof. J. S. Mitchell

Canada

Dr. J. D. Babbitt
Dr. A. J. Cipriani
Mr. A. K. Longair
Dr. R. Taylor

United States

Dr. A. J. Brues
Dr. J. G. Bugher
Dr. M. Eisenbud
Prof. G. Failla
Dr. J. C. Hamilton
Mr. J. W. Healy
Dr. L. Hempelmann
Dr. W. H. Langham
Dr. L. D. Marinelli
Dr. K. Z. Morgan
Dr. H. H. Plough
Dr. L. S. Taylor
Dr. S. Warren
Dr. F. W. Western

The published record of these conferences was nil until 1984. There were minutes of the Chalk River Conference prepared by each delegation, which differed in emphasis and detail. The two succeeding conferences appear to have more uniform sets of minutes, each carefully marked as containing only the *unclassified* part of the official minutes. These minutes found their way around by personal communications. Mine came from John Hursh, K. Z. Morgan, and L. S. Taylor, to whom I am grateful.

The hiatus in published information concerning these conferences was cleared in 1984 by publication of a full documentation prepared by Lauriston S. Taylor as cited earlier (Taylor 1984). This volume contains not only the minutes referred to above, but many letters and other communications. They include early calculations of standards for drinking water cited in a previous chapter. We owe much to Dr. Taylor for unearthing and collecting this important material and to Bruce Church of the Department of Energy (DOE) for arranging its publication.

These conferences began the system for handling radionuclides used for over two decades as presented in ICRP/NCRP reports. Also "standard man," a lung model, and other important innovations started here. Still more amazing is that the quantum jump occurred at the Chalk River Conference, one of only two days' duration! The others, while important, seemed to be fine-tuning the bold steps taken at the first meeting. It must have been an inspired group and/or one presenting ideas that had been incubating for many years during World War II.

Note that all of this got arranged on an essentially ad hoc basis.

5. The Federal Radiation Council

The FRC was a product of the problems of fallout (chapters 12 and 13). It was officially based in the U.S. government, but it utilized, on an ad hoc basis, a considerable number of talented scientists from numerous laboratories, private and public.

As the ramifications of the fallout controversy spread, more and more agencies of the federal government were drawn in. It was no longer the Atomic Energy Commission (AEC) or even the AEC and the Public Health Service (PHS) (see chapter 12). In 1959, by Public Law 86-373, the FRC was formed "to advise the President with respect to radiation matters, directly or indirectly affecting health, including guidance for all Federal Agencies in the formulation of radiation standards and in the establishment and execution of programs of cooperation with the States . . ." Officially, the council consisted of the Secretaries of the Department of Agriculture; Department of Commerce; Department of Defense; Department of Health, Education and Welfare (HEW); Department of Labor; and the chairman of the AEC. The special assistant to the President for Science and Technology was also included ex officio. A chairman was designated by the President "from time to time" from among the members of the council.

Obviously, these individuals could not do the technical work themselves. Each agency nominated delegates to a Working Group. A secretary of the council was designated from senior staff of a participating agency, usually HEW. A professional secretariat was organized. The Working Group then undertook specific projects by using staff detailed from the member agencies and, as urged by PL 86-373, consultation with qualified scientists in biology and medicine and in the field of health physics, including the president of the National Academy of Sciences (NAS), the chairman of the NCRP, etc. A considerable number of scientists were requested to present data, ideas, and opinions to the council and did so willingly.

Since the work of the council revolved primarily around fallout problems, most of its activities involved radionuclides either directly or by implication. The council issued detailed reports. Summaries were placed in the *Federal Register* as a "Memorandum for the President" according to the statutory responsibility. They contained recommendations over the signature of the chairman of FRC. The *Federal Register* item was always followed by a statement signed by the President, which approved the recommendations "for the guidance of Federal agencies." Thus, the FRC was almost a regulator for the federal establishment. However, we will view it as primarily an advisor, since its recommendations were always in the form of "guides" or some similar appellation.

The council was a very active and effective force. It urged more vigorously than anyone before the importance of evaluating biological risk in comparison to the benefits of a given activity in an overt act of optimization. Its recommendations were directed much more at potential population exposures than those of either ICRP or NCRP at the time. Furthermore, the terminology was altered from "maximum permissible exposure" or "concentration" to "radiation protection guides." The guides for radioisotopes were frequently given in three progressively rising ranges, each of which called for more vigorous action.

Because of problems in the actions of some states in response to contamination from fallout, the FRC found it necessary to develop a separate set of guides called "protective action guides" to apply specifically to action in case of environmental contamination. The substance of these problems and of this development is contained in chapter 12.

In its relatively short existence, the FRC produced eight reports (FRC 1960; FRC 1961; FRC 1962; FRC 1963; FRC 1964a,b; FRC 1965; and FRC 1967). There were also three advisory reports from the NAS (FRC-NAS 1964; FRC-NAS 1966; and FRC-NAS 1968).^(a)

The first two FRC reports emphasized background material. Report No. 1 was very general; Report No. 2 was more concentrated on radioactive materials deposited in the body as a result of their presence in the environment.

Report No. 3 was a preliminary evaluation of radiation doses and possible health effects of the fallout from atmospheric weapons testing through 1961.

Report No. 4 took into account the additional testing by both the USSR and the United States through 1962 and went further into evaluation of the suitability of foodstuffs for human consumption, prediction of future levels of radioactivity, etc.

Report No. 5 developed the background for protective action guides and applied the philosophy to ¹³¹I.

In Report No. 6, the fallout estimates made for 1963 were verified, and revised estimates were made for 1964 and 1965, including global amounts and amounts in total diet and various dietary components.

Report No. 7 presented more background material for the development of action guides and included protective action guides for ⁸⁹Sr, ⁹⁰Sr, and ¹³⁷Cs.

The scientific impact of Reports No. 3, 4, 5, 6, and 7 has been reviewed in the discussion of fallout in chapters 12 and 13. The basic guides in Reports No. 1 and 2 utilized the same key figures as in recommendations of NCRP and ICRP that had already been built into the Code of Federal Regulations. However, there was much emphasis in Report No. 1 on derived guides, such as body and organ

(a) The full titles are given in the reference section.

burden, radioactivity concentration guides, the determination of body burdens, etc. In Report No. 2, the guides were given for ^{131}I , ^{89}Sr , and ^{90}Sr in terms of the three ranges. Range I always included zero.

By the middle 1960s, the problems of the uranium miners on the Colorado Plateau finally received the degree of attention from the federal establishment they should have had earlier (see chapter 3). The FRC helped to organize and took part in several conferences on the subject, some of them international, e.g., the Technical Advisory Conference on Uranium Mines, TACUM. They contracted for yet another advisory report from the NAS, this one on radiation exposure of uranium miners. Even prior to this last advisory report, FRC Report No. 8 appeared. It contained guidance for the control of radiation hazards in uranium mining. Details are in chapter 3, along with the citation.

Unfortunately, the first seven reports issued as staff reports of the FRC do not name the staff, although they occasionally acknowledge advice from individuals. Fortunately, the two NAS advisory committees that contributed to these reports can be named.

Membership of NAS Committee preparing working paper on strontium and cesium (FRC-NAS 1964) (pertinent to FRC Reports No. 2 and 7):

Arthur C. Upton, Chairman	Samuel P. Hicks
Howard L. Andrews	Brian MacMahon
Victor P. Bond	Joseph E. Rall
Cyril L. Comar	Eugene L. Saenger
James F. Crow	Shields Warren

Membership of NAS Committee preparing special report to the FRC on *Pathological Effects of Thyroid Irradiation* (FRC-NAS 1966) (pertinent to FRC Reports No. 2 and 5):

Shields Warren, Chairman	Leo K. Bustad
Subcommittee on Effects of	Cyril L. Comar
Radiation on the Thyroid Gland	Louis H. Hempelmann
Howard L. Andrews	Albert W. Hilberg
Victor P. Bond	

Membership of NAS Committee preparing a special report to the FRC on *Radiation Exposure of Uranium Miners*, (FRC-NAS 1968) (pertinent to FRC Report No. 8):

Cyril L. Comar, Chairman	Averill A. Liebow
Subcommittee on Radiation	Brian MacMahon
Exposure of Uranium Miners	Paul E. Morrow
Howard L. Andrews	Eugene L. Saenger
Victor P. Bond	Shields Warren
George W. Casarett	

Throughout, there was a standing advisory committee of the NAS to the FRC. The members were:

C. L. Comar (Chairman), Cornell University
 S. Abrahamson, University of Wisconsin
 H. L. Andrews, Puerto Rico Nuclear Center
 (Formerly at National Institutes of Health)
 V. P. Bond, Brookhaven National Laboratory
 G. W. Casarett, University of Rochester

L. H. Hempelmann, University of Rochester
S. P. Hicks, University of Michigan
B. MacMahon, Harvard School of Public Health
J. E. Rall, National Institutes of Health
W. L. Russell, Oak Ridge National Laboratory
E. L. Saenger, University of Cincinnati
S. Warren, New England Deaconess Hospital

Fortunately, the eighth and final report gives full details of staff as well as the Working Group and all of the NAS Advisory Committee and panels. Those not listed earlier are given below:

Federal Radiation Council

Members

Secretary of Health, Education and Welfare (Chairman)
Secretary of Agriculture
Secretary of Commerce
Secretary of Defense
Secretary of Labor
Chairman, Atomic Energy Commission
Special Assistant to the President for Science and Technology (Adviser)

Staff

P. C. Tompkins, Executive Director
C. C. Palmiter, Special Assistant

Working Group

H. N. Doyle, Department of Health, Education and Welfare
G. M. Dunning, Atomic Energy Commission
W. Mann, Department of Commerce
H. B. Mitchell, Department of Defense
J. P. O'Neill, Department of Labor
A. B. Park, Department of Agriculture
R. G. Stott, Department of the Interior
J. G. Terril, Jr., Department of Health, Education and Welfare
E. C. Van Blarcom, Atomic Energy Commission
F. Western, Atomic Energy Commission

Ad hoc panels of the NAS in addition to those named and to the standing Advisory Committee to FRC are:

Ad Hoc Panel

Mining Practice and Economic Factors

E. C. Van Blarcom (Chairman), Atomic Energy Commission
H. N. Doyle, U.S. Public Health Service
R. D. Evans, Massachusetts Institute of Technology
G. A. Franz, Jr., Colorado Bureau of Mines
D. A. Holaday, U.S. Public Health Service
C. R. Jensen, New Mexico Department of Public Health
J. P. O'Neill, Department of Labor
J. T. Sherman, Atomic Industrial Forum, Inc.
R. G. Stott, U.S. Bureau of Mines
J. Westfield, U.S. Bureau of Mines

Epidemiology

A. W. Hilberg (Chairman), U.S. Public Health Service
V. E. Archer, U.S. Public Health Service
M. A. Connell, Grants Clinic (Grants, New Mexico)

F. E. Lundin, Jr., U.S. Public Health Service
 D. A. Morken, University of Rochester
 H. M. Parker, Battelle, Pacific Northwest Laboratories
 G. Saccomanno, St. Mary's Hospital (Grand Junction, Colorado)
 R. Seltser, The Johns Hopkins University
 B. O. Stuart, Battelle, Pacific Northwest Laboratories
 J. K. Wagoner, Harvard School of Public Health

Review of Dosimetry and Biological Models

H. M. Parker, Battelle-Northwest, Pacific Northwest Laboratory

When the Environmental Protection Agency (EPA) was created in 1970, the functions of the FRC were assimilated into the EPA Office of Radiation Programs. The EPA organized an advisory committee (The Radiation Exposure Advisory Committee, REHAC), which functioned for a while. It was chaired by Roger McClellan, Lovelace Foundation. Later, general reductions in federal funding led to dissolution of this and many other advisory committees. The EPA operated in a different mode anyway and made much more use of the statutory public hearing mechanism than the old system of advisors and advisory committees. Some excellent hearings were conducted. We have had occasion to cite these in earlier chapters and will describe briefly the EPA's general role in standard setting for radionuclides in a later section.

During the administration of President Carter, as part of a review of radiobiological knowledge, the need was voiced to have again multiagency input into the standard-setting process. An attempt was made to devise an organization patterned after the FRC. It even reached the *Federal Register* in February 1980 under the title "Radiation Policy Council." However, the budget cuts of the early 1980s did not allow any such expansion.^(a)

We have examined the general contributions of the FRC in some detail because they are not as well known or as easily found as some of the other enterprises we have examined. A general description of their mode of operation is seen in section III G. Specifics are quoted in the pertinent chapters.

Many of the ideas and most of the limits recommended by FRC are still in use in one way or another; some have never been rescinded. Also, the FRC's influence has been continued by virtue of frequent quotation. It had an important influence in the radioisotope field by pioneering work on many of the environmental problems and procedures we now consider commonplace, and in unifying the activities of the federal establishment to the extent possible.

6. The U.S. Public Health Service's Bureau of Radiological Health, National Advisory Committee on Radiation

Throughout earlier chapters, we have seen specific contributions of the U.S. PHS both by their personnel and as an organization (see chapter 3 on uranium miners and chapters 12 and 13 on fallout problems). There was, of course, much research support, both extramural and intramural, at the National Institutes of Health, most of which concerned basic radiobiology.

(a) After the cutoff date for this chapter, another federal group was organized around these same problems—the Committee on Interagency Radiation Research and Policy Coordination (CIRRPC). It seems to be making some progress.

In a development that we can only mention, the HEW, via the PHS, entered in 1958 the arena of population exposures as well as instrumentation and methodology, first by sponsorship of a laboratory in Cincinnati and later a division, soon renamed Bureau of Radiological Health with satellite laboratories. This group did not dip very far into standard setting per se. They did do invaluable work in the field of assessment, particularly around the problems of fallout, in epidemiology of direct bearing on the verification of standards, in developing methodologies, and in fostering education and training.^(a) For many years, the Bureau of Radiological Health had an advisory committee, chaired by Russell Morgan, professor of Radiology at The Johns Hopkins University, that served some of the same functions as the NAS advisory committee to the FRC. This group, called the National Advisory Committee on Radiation (NACOR), got caught up in some of the controversies surrounding fallout, population exposures in general, and the basic impact of all uses of radiation on the public health. This included medical and commercial applications. NACOR issued several reports calling attention to needs for radiation protection. Members of this committee during the 1960s included:

Russell H. Morgan, The Johns Hopkins Medical School, Chairman
 John H. Barr, Tufts University
 Victor P. Bond, Brookhaven National Laboratory
 Richard H. Chamberlain, University of Pennsylvania Hospital
 Cyril L. Comar, Cornell University
 James F. Crow, University of Wisconsin
 Ralph E. Dwork, Ohio State Department of Health
 Howard C. Eberline, Eberline Instrument Corporation
 Alexander Grendon, University of California
 Herman E. Hilleboe, New York State Department of Health
 Leon O. Jacobson, Argonne Cancer Research Hospital
 Hardin B. Jones, University of California
 Roscoe P. Kandle, New Jersey State Department of Health
 Edward B. Lewis, California Institute of Technology
 Berwyn F. Mattison, American Public Health Association
 Russell I. Pierce, U.S. Public Health Service
 Blucher A. Poole, Indiana State Board of Health
 Laurence L. Robbins, Massachusetts General Hospital
 William J. Schull, University of Michigan
 Wendell G. Scott, Washington University
 J. Newell Stannard, University of Rochester
 Lauriston S. Taylor, National Bureau of Standards

7. The U.S. National Academy of Sciences-National Research Council

We have already seen the frequency with which the academy was consulted by federal agencies and have seen some of the advisory committees that were appointed. During the height of the fallout events, the academy was requested to provide technical information to both the scientific community and the

(a) Many of the environmental functions of the Bureau went to EPA in 1970. The others remained, partly under the auspices of the Food and Drug Administration.

general public on all aspects of radiation usage and effects. This began in 1956. Detlev Bronk, who was president of the Rockefeller Institute in New York at the time, but had spent much time with the academy, lifted the proceedings completely out of the governmental arena by arranging financial support from the Rockefeller Foundation. The work began in 1955, and summary reports were issued in 1956.^(a) They bore only obliquely on standards.

In 1960, a series of reports was issued covering all aspects of the Biological Effects of Atomic Radiation, known as the "BEAR" reports and authored by the "BEAR" Committees. There were six basic areas, each represented by a committee: genetic aspects, agriculture and food supplies, meteorological aspects, disposal and dispersal of radioactive wastes, oceanography and fisheries, and pathologic effects. The only ones of direct concern to the radionuclide standards field were subcommittees of the Committee on Pathologic Effects. These were as follows:

Subcommittee on Internal Emitters

Austin M. Brues, Argonne National Laboratory, Chairman
 Thomas F. Dougherty, University of Utah
 Miriam P. Finkel, Argonne National Laboratory
 Hymer L. Friedell, Case Western Reserve University
 Wright H. Langham, Los Alamos Scientific Laboratory
 Kermit H. Larson, University of California at Los Angeles
 Herman Lisco, Argonne National Laboratory
 William P. Norris, Argonne National Laboratory
 J. Newell Stannard, University of Rochester
 Joseph D. Teresi, U.S. Naval Radiological Defense Laboratory, San Francisco
 Roy C. Thompson, General Electric Company, Richland, Washington
 Raymond E. Zirkle, University of Chicago

Subcommittee on Inhalation Hazards^(b)

Harry A. Kornberg, General Electric Company, Richland, Washington, Chairman
 W. J. Bair, General Electric Company, Richland, Washington
 Stanton H. Cohn, Brookhaven National Laboratory
 C. C. Gamertsfelder, General Electric Company, Cincinnati
 J. W. Healy, General Electric Company, Richland, Washington
 Francis R. Holden, Radiation Detection Company, Palo Alto
 James K. Scott, University of Rochester
 J. Newell Stannard, University of Rochester
 George V. Taplin, University of California Medical Center, Los Angeles

These reports did address directly the adequacy of standards. They also contributed indirectly by addressing research needs. All were oriented toward the evaluation of hazards. The pertinent reports, for our purposes, are referenced in chapters 9 and 13 and by Bell (1977).

As the fallout furor decreased, the BEAR committees were disbanded. However, the growing concern over the effects of very low levels of ionizing radiation on populations led to new requests to the National Academy of Sciences-National Research Council (NAS-NRC). These committees (funded by the EPA) began work in the early 1970s. Their reports were known as "BEIR"

(a) All of these are listed by Bell (1977). They covered the waterfront from radiobiology through transportation to waste disposal.

(b) A photograph of the Inhalation Hazards Subcommittee taken at one of its meetings is shown as figure 16.1.

FIGURE 16.1. Photograph of the Subcommittee on Inhalation Hazards of the National Academy of Sciences–National Research Council BEAR Committee taken in the early 1960s. Seated from left to right: W. J. Bair, F. R. Holden, H. A. Kornberg, J. K. Scott, J. W. Healy and standing: S. H. Cohn and J. N. Stannard. Note: Despite diligent efforts, we have been unable to identify the lady to Mr. Healy's left. (Photo courtesy of Pacific Northwest Laboratory.)

reports for “Biological Effects of Ionizing Radiation” and the committees as the “BEIR” committees. The first and third have been quoted liberally in previous chapters and will be later in this one. The second report concerns primarily benefit-cost relationships in the radiation field.

BEIR reports I and III have addressed specifically the assessment of risk to man from low-level exposures to ionizing radiation. Since the standard-setting process is moving more and more to a risk-based system, these reports have had much use by those concerned with setting standards for radioisotopes. Unfortunately, the unknowns have grown with consideration of lower and lower levels. The committee responsible for the third report could not agree on some basic aspects of the dose-response relationship to be applied to the limitation of exposure at very low levels. The result was a majority and a minority report and the promise of further controversy ahead.

A new committee (BEIR IV-alpha), organized in 1985, is the first to deal specifically with radionuclides, in this case, alpha-emitting radionuclides.^(a)

(a) Note added in proof: Its report (BEIR IV) has just been issued (January 1988). It concentrates on radon problems, including a re-examination of the epidemiology discussed in chapter 3 (NAS-NRC 1988).

8. The Congress of the United States

To the extent that the Congress advises everyone by its control of appropriations, it is always present in work such as we are discussing. However, there are two specific aspects of importance to our current topic.

The Joint Committee on Atomic Energy, one of the best features of the Atomic Energy Act, sponsored many hearings that brought scientists from the laboratory and industry together with administrators, regulators, and law makers around problems of the adequacy of our present standards for radiation exposure and our knowledge of radiobiological effects. The transcripts provide an invaluable resource, as we have seen (e.g., Congressional hearings 1963).

The U.S. Congress also had an influence on the whole process of standard setting and evaluation by its passage of the National Environmental Protection Act (NEPA) in 1970. In this they were behaving more as regulators than advisors. Hence, this activity will be reserved for section II B.

9. The Professional Societies

The radiological societies very early developed ways to have input to the practices of radiation protection. Many had formal committees on the subject. Of most pertinence to standards for radionuclides are the activities of the Standards Committee of the Health Physics Society and of the American Nuclear Society. In addition to general matters, these committees have contributed, even worked in close collaboration with, federal groups to devise methodologies and philosophies for assessment, e.g., in bioassay for radionuclides.

10. Other Activities

The above concerns primarily the United States, except for the discussion of the ICRP. Each country has had its own way of implementing the general recommendations from groups such as the ICRP. Also, each has ways of evaluating performance and focusing new knowledge. A good example is the U.K. National Radiological Protection Board (NRPB).

For the same reasons as lay behind the organization of BEAR, BEIR, and the FRC, the United Nations developed a Scientific Committee on the Effects of Atomic Radiation (UNSCEAR) in 1955. Since then, UNSCEAR has reported yearly to the General Assembly and produced comprehensive reports at irregular intervals: 1958, 1962, 1964, 1966, 1969, 1972, 1977, and 1982. The work was carried out through meetings of specialized scientists, preparation of working papers, and a small scientific staff. These reports primarily evaluate current information and any changes occurring since the previous report. They do not overtly enter the arena of standard setting, but the information is so complete, so authoritative, and so pertinent that it has had much influence on any conclusions regarding risk estimation, dose-response relationships, source terms, etc. They are very complete source books on radionuclides in the environment, both natural and manmade, assessment of doses therefrom, and possible effects.^(a)

The reports themselves are relatively brief, but the appendices are voluminous. The two most recent UNSCEAR reports (UNSCEAR 1977, 1982) are cited

(a) The authors of these comprehensive reviews did not find reasons for significant changes in the basic standards underlying radiation protection.

for convenience in the bibliography. Through these, the reader can explore earlier reports.^(a)

B. The Regulators

It is not our purpose or need to review the development of regulations. We do need to consider the uses made by regulating bodies of the research data developed at such cost in money and careers.

1. The U.S. Atomic Energy Commission

The AEC was the first major regulator^(b) for radioisotopes. The major documents appeared as parts of the U.S. Code of Federal Regulations. They were primarily directed at the large contractors of the AEC and, as the program for peaceful uses of atomic energy grew, at the licensees also.

The regulators in the AEC days did not agonize so much over the basic permissible levels as they did over quantitative behavior of radioisotopes in and around the various installations and their excretion by man. The Code of Federal Regulations Part 20^(c) utilized primarily the NCRP/ICRP 1959 recommended values to construct a large table of maximum permissible concentrations (MPC). They added a second set of values for exposures of the general population (see section IV D).

When the problems of the movement of radionuclides through the environment became paramount, the AEC found it necessary to revise the MPC values for certain radionuclides. For example, the value for iodine was reduced by a factor of seven hundred because of concentration in the food-milk chain (see chapter 15). This applied to light-water-cooled reactors. This and other changes have appeared in Appendix I and elsewhere. As the levels in Appendix I have been lowered, standards for radionuclides have become more and more likely to control operations.

2. The U.S. Nuclear Regulatory Commission

When the AEC was disbanded in the mid-1970s, its regulatory functions went to the Nuclear Regulatory Commission (NRC) for the large sources and to the Food and Drug Administration (FDA) for items like medical radionuclides. The basic criteria did not change markedly, nor did the Code of Federal Regulations. The modifications came out principally as "Regulatory Guides," which covered nearly every aspect of operating or building nuclear energy installations. There were some interim changes in basic levels. Now, however, a thorough reworking of the Code of Federal Regulations is under way. The NRC is keeping in close touch with all groups working on revisions of radionuclide standards, and vice versa.

(a) Still another report was issued while this book was in proof.

(b) The MED was, strictly speaking, first, but this was self-regulation within a tightly circumscribed group.

(c) There are over 70 Parts to Title 10 of the Code of Federal Regulations. Most of them concern practical and operational aspects.

3. The U.S. Environmental Protection Agency

Technically, the EPA has jurisdiction over any and all releases to the environment. Details of the management and construction of large nuclear installations are the province of the NRC. Many of the medical and research radioisotopes, both preparation and use, come under the FDA.^(a) However, this is delegation of details. Ultimate responsibility for environmental standards resides in the EPA.

The EPA has much interest in standards for ambient air and for drinking water (chapter 15). Some very fine scientists and a competent NAS committee helped EPA develop a basic document on Quality Criteria for water (EPA 1976), which formed the basis for judgment in EPA and state programs associated with water quality. In the radioisotope field, the EPA seems to have been and to be concentrating on standards for drinking water (as we saw in chapter 15). There have been many hearings and proposals made in the *Federal Register*. The procedure includes developing a "criteria document" that analyzes the information available and theoretically leads inexorably to conclusions regarding suitable concentrations of radioisotopes in drinking water. In the terms we will use later in this chapter, their approach is the *direct* one rather than a computational approach. The EPA thus far has tackled primarily important naturally occurring radionuclides such as radium and uranium (chapter 15).

The standards derived by these analyses are, in general, far lower than any previous recommendations. Many groups over the years have examined the data and concluded that there is basically no evidence requiring drastic reductions of the permitted concentrations. Nevertheless, the EPA seems to be listening to a different drummer and can draw quite different conclusions from the same data. This is partly because they felt it advisable to parcel out the risks from different activities. Naturally, these proposed levels encountered opposition from states and local communities, particularly since some of the proposed levels would require expensive treatment of water supplies that have been serving a given community for generations.^(b)

Obviously, the current controversy surrounding the true picture at low levels of radiation (see chapter 21) leads many to support an ultraconservative view. Since the chances of measuring any biological effects at these low levels, even with the very best of epidemiologic studies, is vanishingly small, the final decisions will probably rest more upon economic and social aspects than upon biomedical information. As potential biomedical effects of *routine operations* are analyzed and found to be quite small, the decision rests more and more on the former.

Since details of the current EPA proposals and the arguments pro and con are far beyond the cutoff point of this history, and we are not reviewing all recommendations anyway (except for chapter 15), we will let the discussion rest at this point except to quote a bit of philosophy from the letter foreword to *Quality Criteria for Water* written by E. C. Beck, Deputy EPA Administrator at the time: "It must be emphasized that national criteria can never be developed to meet

(a) There is little information on what use the FDA makes of the accumulated information bearing on standards.

(b) These are not "enhanced" supplies with contaminants introduced by the activities of man. Treatment of them is not questioned so much.

the individual needs of each of the Nation's waterways —the natural variability within the aquatic ecosystem can never be identified with a single numerical value." (EPA 1976)

4. The U.S. Congress, the Environmental Impact Statement

The Congress became a regulator of radioisotope exposure in the later 1960s. The Baltimore Gas and Electric Company planned to build a nuclear power station at Calder Cliffs on Chesapeake Bay. There was much opposition from various local and national groups. The AEC, which had the licensing authority in those days, declared the plan safe. There was enough agitation, however, to move Congress into action. By passage of the National Environmental Policy Act in 1970, the Congress imposed a much more detailed examination of all aspects of the plan, especially environmental aspects, upon a federal agency, the AEC. This was indeed a landmark decision. It applied to any and all activities with potentially significant environmental impact, not just sources of ionizing radiation.

Thus was generated the *Environmental Impact Statement* (EIS). Among other things, this and other analyses in the radioisotope field showed that solid or potentially solid radionuclides were probably the most important potential radioactive contaminants of the environment, and some attention was drawn away from the noble gases.

The statement required even more detailed ecological investigations *prior* to construction than the fairly stringent AEC regulations. Also, statements were required on much more than the radiological impact, e.g., economic, sociologic, and other impacts.

In the ensuing years, thousands of pages have gone into EISs for each planned or active nuclear installation, as well as thousands of other developments.^(a) These were filled with calculations for the behavior of radionuclides in the plant and in the environment of the specific site. They entailed expenditure of thousands of man-hours by good people. In general, state-of-the-art knowledge was used, and it did not differ fundamentally from the basic criteria we will discuss in this chapter. Indeed, not long after the NRC became the recipient of such statements, guidelines for their preparation were set up that discouraged application of any marked originality by anyone hoping to be licensed in a finite time!

The submission of an EIS was usually followed by a hearing or hearings. The statements themselves and the transcripts of the hearings are a gold mine of information, much of it applicable to the standard-setting process. Perusal of these gives a cross section of what was on people's minds at various points along the way.

It is most unfortunate that these documents are not readily available and that they have not been combed in a scholarly manner to extract the essence of the thinking involved. They are much too ponderous and site specific as they stand. Unfortunate, too, is the fact that once a license was granted the all-important statement was put in a file or even discarded.

(a) This activity was large enough to become the subject of a "handbook" written by Cheremisinoff and Morresi (1977 with fourth printing in 1980). It lists almost thirty areas of concern for the preparation of an EIS and gives examples from air quality to waste disposal. Nuclear facilities are included but are not as major a participant as the furor might predict.

For the purposes of this chapter, we can only say that ideas, especially regarding environmental transport, gradually evolved through these statements. This may be the chief *scientific* contribution of the EIS.

Probably the Congress benefited the standard-setting process for radionuclides by starting this activity. However, it now seems there could have been an easier way.

5. The States

Traditionally in the United States, matters of worker health have been the responsibility of the states. Traditionally also, the PHS has stood ready to provide information and assistance to the states, but it never intruded. Exposure standards to chemical toxicants were set largely by industry and professional societies or groups like the American Council of Governmental Industrial Hygienists.

In the nuclear energy field, the secrecy of the MED and the provisions of the Atomic Energy Act took much of this responsibility away from the states. This included responsibility for radionuclides. Only in the case of naturally occurring radioisotopes was there some of the old system. We saw in chapter 3 how this dichotomy worked against the health of the uranium miners.

Yet, the states generally have excellent departments of health and of labor, and they prepare codes for industries within their borders. In general, these codes have been patterned after the federal codes. In fact, some of the people involved in standard setting at the federal level were called in to advise their home state in the development of codes.

There have been a few instances where a state decided to apply stricter codes than promulgated by, for example, the AEC. An example of this occurred in Minnesota in 1967 to 1969.^(a) The Northern States Power Company wished to construct two large nuclear reactors on the Mississippi River near Monticello, Minnesota. The Minnesota Pollution Control Agency (MPCA) was given powers by the governor to regulate discharges from nuclear power plants. After many hearings and consultations, the permissible discharge level was set lower than those promulgated by either the AEC or the FRC. This was partly on the theory that the Mississippi River acted as a drinking water supply for hundreds of towns downstream and many reactors were being planned on its banks. The action touched off a nationwide controversy and a suit from the Power Company against the MPCA. In its midst, the University of Minnesota sponsored a symposium, "Nuclear Power and the Public," (Foreman 1970) which brought together people from a variety of disciplines and a variety of backgrounds. The central theme was evaluation of health hazards to the public from nuclear reactors, but of almost as much importance was the "preemption" of state regulatory responsibilities regarding releases of radionuclides from nuclear power plants by the federal establishment. Throughout the symposium proceedings, there are allusions to the basic knowledge needed for the standard-setting process, e.g., Auerbach (1970), Commoner (1970), Eisenbud (1970), and Stannard (1970). There were also penetrating general discussions of energy policy.

A similar symposium with the same title was held at the University of Wisconsin some months later.

(a) We saw the consequences of state actions regarding fallout in chapter 12.

As we all know, the states did not have unique information to put into their standard-setting process, only unique points of view. In the case of nuclear power plants, the federal guidance prevailed.

There may be another polemic developing. In this one, the states want *higher* permitted levels than the federal proposals. Many of the states are balking at the proposed drinking water standards for radioisotopes coming from EPA (chapter 15). They are using the same basic data but finding no biomedical reason to go so low and no economic benefit in having to treat water supplies unnecessarily (Hazle 1982). A further aspect is the fact that the analytical laboratories of the cognizant departments of the states are now quite competent. Sometimes they do not get the same answers as the EPA for current concentrations of naturally occurring radionuclides in a given water supply.

If pressures increase toward ever lower radioisotope concentrations in water or air, there are conflicts with states, even with municipalities, ahead. One reason is that the states see areas in the chemical toxicity realm where action and resources are more needed. As a result, many of the individuals with expertise in the radioisotope field are finding a need to learn about the standard-setting process for chemical toxicants.

So much for the organizations involved. Let us now consider the uses of the research data in standard setting.

III. Direct Derivation of Standards for Radionuclides

In the field of industrial hygiene and toxicology, it has been common practice, especially in the decades before organizations like National Institute of Occupational Safety and Health, Occupational Safety and Health Administration, etc., to develop standards on the basis of in-plant experience. This usually meant that the development of symptoms and of overt injury called attention to the presence of a problem. In retrospect the concentrations of the noxious agent in areas where cases of injury developed were compared with those in "safe" areas. A standard was developed, frequently with the interposition of a safety factor and the assumption of a threshold dose or concentration below which no effect would be expected. The early standards for protection from x rays and the gamma emissions from ^{226}Ra used this same approach, viz., determination of a safe level and the doses therein. We will term this use of information in retrospect "direct determination of standards."

The first standard for a radionuclide was developed by the direct method, although in somewhat modified form since the measurements were of body burden rather than air concentrations. This is the bench-mark figure for ^{226}Ra .

A. The Radium-226 Standard

The general characteristics of ^{226}Ra and the experience, both research and clinical, with the dial painters, radium chemists, radium patients, and others have been detailed in chapter 1. The story of how the research data were used to develop the first standard for a radionuclide has been told graphically on several occasions, especially by Robley Evans. His most readily available review is from the Health Physics Society Silver Anniversary Symposium (Evans 1981). The Kathren-Ziemer volume contains another summary by Evans, which places greater emphasis on instrumentation and methodology (Evans 1980).

The circumstances for development of this first standard were somewhat unusual. The saga of the dial painters had unfolded, and new information was coming in regularly, particularly from and to the Massachusetts Institute of Technology (MIT) group. When U.S. entry into World War II looked all but inevitable, the U.S. military establishment became engaged in production of large numbers of radium-dial instruments. The U.S. Navy took the lead in assuring that the dial-painting experiences of World War I would not be repeated. Evans reports that a Captain C. Stephenson visited his laboratory at MIT in 1940. He urged that they provide safety standards for radium and luminous paint. Indeed, if such standards were not forthcoming in a reasonable time, Evans would be inducted into the Navy and assigned to production of standards! Evans did not need prodding of this magnitude, but it helped overcome some of the inevitable inertia of getting some sort of consensus from those concerned.

In view of the stated needs, an advisory committee was established under the Advisory Committee on X-Ray and Radium Protection of the NBS (see section II) to develop materials on the safe handling of radioactive luminous compounds. As Evans (1981) describes the events, a decision regarding the maximum permissible body burden for ^{226}Ra was arrived at on the basis of experience with twenty-seven persons who had been studied in depth:

By February 1941 we had a total of some 27 persons with accurately measured body burdens, all of whom had been measured at MIT or in New Jersey with MIT apparatus. We had observed 7 persons with residual body burdens below $0.5\ \mu\text{Ci}$ and no injuries, whereas some 20 persons with residual burdens of $1.2\text{--}23\ \mu\text{Ci}$ showed various degrees of injury.

After reviewing these 27 cases, and noting that we were obliged to make an "informed judgment" decision, I suggested that we should set the "tolerance level" for residual radium burden in radium-dial painters at such a level that we would feel perfectly comfortable if our own wife or daughter were the subject. I then asked each of the other 8 committee-men individually in turn if he would be content with $0.1\ \mu\text{Ci}$. Unanimously, we all were.

Thus $0.1\ \mu\text{Ci}$ of ^{226}Ra residual body burden was adopted in NBS Handbook 27 which was issued 2 May 1941, some 7 months before Pearl Harbor, 2 months after the then-secret discovery of plutonium, and 18 months prior to the first demonstration of a nuclear reactor.

(From Evans 1981, pp. 442-443)

So the first standard for a radioisotope came directly from data on and experience in humans.^(a,b) It was published as NBS Handbook H-27 (1941). The sequel and the fact that a large factor of safety was involved can be seen also in Evans's remarks:

- (a) It might be remarked that the criterion of considering the "tolerance level" in terms of one's own wife or daughter indicates that chivalry was still alive in 1941.
- (b) The decision makers were: L. F. Curtiss, National Bureau of Standards (chairman); R. D. Evans, physicist, MIT; G. Failla, physicist, Memorial Hospital, New York; F. B. Flinn, industrial hygienist, Columbia University; H. S. Martland, physician, medical examiner of Essex County, New Jersey; J. E. Paul, Radium Corporation of America, New York; J. S. Rogers, U.S. Department of Labor; Capt. Charles S. Stephenson, physician, Bureau of Medicine and Surgery, U.S. Navy; Col. G. T. Taylor, Radium Chemical Company, New York. Note that the instigator and advocate, Capt. Stephenson, was folded into the decision-making process!

After World War II, NBS Handbook 27 was designated as NCRP Report 5, and also the ICRP adopted the 0.1 μCi permissible burden. Now, 39 yrs later, and with more than 2000 radium patients studied at MIT, New Jersey, the Argonne Cancer Research Hospital and the ANL Center for Human Radiobiology, no exception has been found to the 0.1 μCi residual radium standard as an innocuous body burden.

The 0.1 μCi Ra bench mark was based on the residual body burden of patients, long after they had acquired a much larger initial burden, commonly the order of 100 times larger. When used as a radiation protection guide the 0.1- μCi bench mark represents not a residual burden but the maximum body burden reached during intake. Thus there is a substantial additional safety factor of between 1 and 2 orders of magnitude built into the conventional use of the 0.1 μCi Ra standard as a maximum body burden rather than as a residual body burden evaluated many years after exposure. (From Evans 1981, p. 443)

This standard has withstood constant reevaluation as more and more data have accumulated (Evans 1967b, and numerous works cited in chapter 1 as well as the 1981 summary). This includes current work under way at Argonne National Laboratory (ANL).

Further along, Evans discusses the appearance of eye lesions from radium in the beagle dog (see chapter 1) and the marked difference in apparent sensitivity of rodents compared to man for a large number of substances. In the early MIT work with rats (see chapter 1), to produce a crop of tumors, the Wistar rat required a skeletal concentration of radium far above that known to produce bone cancers in man. This led to Evans's well-known dictum, reiterating Pope's: "The proper subject for the study of man is man."

We will see examples in subsequent sections of how this dictum can be applied without engaging in experimental effects work in humans. That would be unthinkable.

Meanwhile, it is interesting to note that the data on ^{226}Ra from the large beagle dog experiments described in earlier chapters of this book have been shown to contribute significantly to evaluating the dose-response relationship in humans. Work by Otto Raabe and colleagues at the University of California at Davis (Raabe, Book, and Parks 1980) correlates the response ratios with the normal life expectancies of mice, dogs, and humans. The correlation was good and brings the beagle data in sight of direct application to standards rather than through the toxicity ratio procedure which we discussed in chapters 7 and 8. Further, the University of California at Davis group (Raabe, Parks, and Book 1981) described dose-response relationships for bone tumors in beagles exposed to ^{226}Ra and ^{90}Sr based on lifetime experiments and compared them with those for mice and men. They found a marked effect of dose rate with a much smaller average cumulative radiation dose to death for those individuals that died of bone cancer at low dose rates, i.e., small body burdens. The dictum that the proper subject for the study of man is man was reiterated in the University of California at Davis work. Mice required only one-tenth as long and dogs only about one-third as long to develop bone tumors at a given dose rate as people. The response ratios correlated well with normal life expectancies.

As if in response to the admonition to stick with people, the group at the Center for Human Radiobiology developed a comprehensive summary of the dose response for production of bone sarcomas in female radium-dial painters. The work was presented at the International Conference on the Radiobiology of Radium and the Actinides held at Lake Geneva, Wisconsin, in October 1981. Here Rowland, Stehney, and Lucas (1983) drew generalized dose-response functions from a population of 3,055 women identified as having been dial

painters at one time or another. There were two subpopulations, one based upon year of entry into the industry and the other upon date of first measurement. Dose-response functions consistent with ideas developed from much earlier work could be fitted to the data. Risks could be derived directly from these dose-response functions.

While the entire story is much more sophisticated now than in 1941, the results in no wise counter in any serious way the validity of the standard then based on approximately a hundred times fewer people.

B. Standard for Radon-222

The basic dosimetric and biomedical problems associated with the first decay product of ^{226}Ra (^{222}Rn) and of its subsequent daughter products and their historical development were traced in chapter 3. Only a little was said there about the derivation of the original standards for radon. We will repeat in part and expand here on what was said there.

The standard for radon presents another example of one generated directly from the data on humans. This time it depended largely on measurements of the exposure environment, since the short half-life of radon and its immediate progeny meant that residual body burdens were usually too low to infer much about initial tissue contents^(a) from excreta measurements and the like. The derivation was much like the classic procedures of industrial hygiene.

Evans and coworkers played an active part in the development of the first radon standard as they did in development of the ^{226}Ra standard. It was based upon measurements of air concentrations of both radon and thoron and represents one of the earliest permissible levels established for radioactive aerosols.

The genesis of the work was the concern of an insurance carrier for a large gas mantle manufacturing company. As described in chapter 4, thorium compounds are used in the manufacture of such mantles, and airborne thorium and thoron were constantly present. The insurance carrier wished an evaluation of the potential health hazards of thoron in these factories. Evans and his colleague, Clark Goodman, at MIT, developed equipment for collecting, in the field, the second daughter product of thoron (thorium B = ^{212}Pb) and sending samples back to MIT for counting. This work demonstrated as early as 1937 the presence of large quantities of thoron in some of the thorium mantle factories (maximum of 4,000 pCi Tn/l; 230 to 4,000 pCi/l range).

Because of the many parallels, it was easy to extend the thinking and the measurements to radon gas. In a classic paper received for publication in 1939 but not published until 1940, Evans and Goodman considered both thoron and radon (although the paper title mentions only thoron) and suggested a safe working concentration for both radon and thoron for plants, laboratories, and offices (Evans and Goodman 1940 and 1980). They started with observations made by Barker in 1934, which suggested that concentrations of either gas above 10^{-11} Ci/l can be injurious over long exposures. They looked at experimental

(a) Attempts to extrapolate back to original exposure by measurement of the longer-lived daughters such as ^{210}Pb or ^{210}Po have been described in earlier chapters. Techniques for such measurements were not available when the first standards were developed for radon. The development of whole-body and in-vivo tissue counting have made this more feasible but still not easy.

work with small animals. They turned also to the lung cancer incidence among workers in the European mines discussed at length in chapter 3 and used the data summarized in table 3.2 of chapter 3 (which was table 3 in the Evans and Goodman paper). This gave radon concentrations in the various mines and in several parts of some mines. They then correlated the levels in the mines and in various shafts of the mines with cancer incidence in miners working therein to the extent possible.

Evans and Goodman used a broad brush to arrive at final figures. These were that long-continued breathing of air containing 10^{-9} Ci/l of either radon or thoron would result in a high incidence of lung cancer, and that exposures should be kept at less than one one-hundredth of this figure viz., 10^{-11} Ci/l or $10 \mu\text{Ci}$ (10 pCi)/l.

This figure was incorporated into the same NBS Handbook (NBS 1941) as the radium standard. It was intended to apply to work rooms rather than mines because there was no uranium miner enterprise in the United States in 1941. Nevertheless, as described in chapter 3, it was taken over later for the mines as well.

The historical record does not indicate whether or not the committee applied the same criterion as was used for radium in making its choice, viz., comfort with having one's own wife or daughter work in such an environment. However, it was the same committee, and presumably their chivalry extended from radium to radon.

There is no doubt that the level adopted was very conservative. Indeed, the permissible levels adopted for mining environments many years later and expressed in Working Levels (WL) (see chapter 3) are higher by a factor of at least ten.^(a) This fact has frequently gone unappreciated in the conversion to the WL system. Also, it represents one of the few instances in which a radiation protection guide developed in the early days was raised rather than lowered in later years.

Application of the WL concept detailed in chapter 3 has in effect drawn the focus of the standard for ^{222}Rn away from radon and placed it in the preformed daughters. This has introduced conceptual and computational steps not present in deriving the original standard or in the usual "industrial hygiene" approach. Fred Cross at Pacific Northwest Laboratory (PNL) (Cross 1979) has pointed out clearly, in a paper recommended to all who wish to delve further, that the WL-unit "ignores the 'form' of the potential alpha energy," e.g., how much comes from daughter products attached to ore dust, diesel smoke, and other vectors versus how much comes from unattached daughters, etc. As a result, as described by Morgan (cited in chapter 3), the radiation dose to the target tissue in rem does not bear a constant relation to WL or Working Level Months (WLM). This phenomenon was pointed out earlier by Morgan (1967) using the terminology of the MPC. He computed ratios of MPC to WL ranging from 0.11 to 170 depending on the properties of the inhaled aerosol. These are extremes, but they illustrate the point. Fortunately, the ratio is not far from unity for most typical mine conditions.

Thus, while it would be more logical, as Cross points out, to base the standards directly on the entities responsible for the biological effect, it seems likely that the WL-WLM concept will persist, possibly with more adjustment for the

(a) Because the Working Level is a much more complex entity, this comparison is very approximate but is basically true.

degree of unalterable R&A. New research and analysis can feed to this just as the earlier research fed to the original radon standard. It will be more sophisticated and not fully within the definition of a direct determination of standards, but close. The epidemiologic contributions remain "direct," of course.

Clearly the standards for radon, while hardly as inexorably derived from measurements of body or tissue burdens in humans and their correlated effects as in the case of radium, still rest largely upon a body of knowledge developed over long periods and involving effects in man. The enormous efforts detailed in chapter 3 have thus been put to much practical use.

C. Possible Interrelation of the Radium and Radon Standards

An interesting coalescence of the basis for the radium standard and that for radon was developed by Robley Evans on the occasion of extensive hearings on radiation exposure of uranium miners conducted by the Joint Committee on Atomic Energy of the U.S. Congress (U.S. Congress 1967). (By this time, the U.S. government knew there were serious health problems among the uranium miners on the Colorado plateau and convened the experts.) In response to a question on what scientific information existed that might contribute to determination of a proper standard for radon and its progeny, Dr. Evans introduced part of a document called CORD (Carcinogenicity of Radon Daughters). CORD contained the idea that carcinomas of the sinus epithelium seen in persons with appreciable radium burdens might be due to radon produced in situ. Evans presented many arguments concerning the basic similarities between the alpha-ray effects from radium in bone and those to sinus and bronchial epithelium from radon. He then presented data showing calculated doses to the sinus epithelium in a case that developed a carcinoma of the left frontal sinus (fifty-two years after radium injections) and measurements in another case that did not develop a carcinoma. These were direct measurements made on the 3.5-cm piece of frontal bone removed surgically with the carcinoma. The patient was cooperative to the point of allowing the surgical opening of the other uninvolved sinus for removal of an air sample. The MIT workers then measured the radon concentration in this air sample. It was thirty times that in the exhaled breath. Using this and information from other cases, Evans suggested that the effects of radon produced in vivo could be used by analogy for radon exposure to the lungs by inhalation (Evans 1967a). Thus, the idea of a direct approach continued in a different context.

There was some discussion that the two types of respiratory epithelium, lung and sinus, were not truly identical (Saccomanno at the same hearings, p. 659 et seq., also Parker p. 666) and about the fact that the radiation dose is partly from the radium in bone underlying the sinus epithelium. Furthermore, an entire appendix to the hearings was devoted to a critique of the CORD document, but further discussion here would get us into areas beyond our scope.

In 1969, an entirely new set of hearings was conducted on "Radiation Standards for Uranium Mining" (U.S. Congress 1969). This brought together nearly everyone from the scientific, administrative, labor, and industrial communities concerned and provides, along with the 1967 hearings, all anyone should ever need to know about what was being done about uranium miner standards and their relation to the radium standard. Although the mass of discussion makes extraction of basic philosophy difficult, it is obvious here too that epidemiologic evidence for effects and dose-response relationships were still at the heart of

any decisions regarding standards for exposure. Problems are in details of the statistics not the basic methodology. Even the most recent considerations by radiation protection organizations such as NCRP, discussed briefly in chapter 3, have the same base.

D. Standards for Natural Uranium

The derivation of standards for natural uranium has involved a mixture of the direct approach, as defined in this section, and the computational approach to be reviewed in section IV. To add complexity, there are two entirely separate endpoints in terms of effect. Because natural uranium is only weakly radioactive and is a moderately potent chemical toxicant to kidney, the process of standard setting has had to consider both chemical toxicity and radiation effects. In general, the direct approach has been applied more to chemical toxicity, while the indirect or computational approach has been applied more to the possibilities for radiation injury. We will emphasize here those circumstances in which the direct approach was used, but we cannot separate them entirely from the circumstances involving the indirect approach.

The basic saga has been told most skillfully by N. L. Spoor and J. B. Hursh in a chapter prepared for the monograph, *Uranium, Plutonium, Transplutonic Elements*, edited by Hodge, Stannard, and Hursh (Spoor and Hursh 1973).^(a) A companion chapter of equal stature in the same volume summarizes the experimental data on man (Hursh and Spoor 1973) and has been cited many times in earlier chapters. A somewhat shorter but crisp and useful summary was given by Hursh (1975) at the Conference on Occupational Health Experience with Uranium held at Arlington, Virginia, in April 1975 (ERDA 1975), under the auspices of the U.S. Energy Research and Development Administration (ERDA). Also, the saga was reviewed briefly by Stannard (1981) as part of a general paper at the Health Physics Society Twenty-Fifth Anniversary Symposium.

In contrast to the development of standards for radium and radon, the direct approach depended largely upon application of data from animals. The data on humans have been useful for validation of the standard, as we will see in section VIII. One reason for this difference is that occupational exposure to uranium in significant quantity had not occurred before the need to establish a standard became urgent.

The first standard was entirely empirical. Let us tell it in the words of Spoor and Hursh:

In 1944, before any experimental work had been completed there was an urgent need, in the Medical Section of the Manhattan Project, for a rough toxicological guide for the safety of those handling uranium in laboratories and plants. As production under war-time conditions had to proceed without delay some working rule had to be adopted immediately. They decided to adopt as the (MPC)_a [Maximum Permissible Concentration in Air] for uranium for occupational exposure the current (MPC)_a for lead, namely 150 $\mu\text{g}/\text{m}^3$. In the lead industry this limit had for a long time (since 1933, in fact) been regarded as an acceptable compromise between the demands of safety and those of engineering feasibility. In applying

(a) Hursh is, as we know, one of the key figures in internal emitter research, and we have seen his work in several chapters of this book. He worked at the University of Rochester. Spoor is a practical health physicist associated with the U.K. Atomic Energy Authority and had much opportunity to observe in-plant operations with uranium.

this figure to uranium there was no suggestion that lead and uranium were alike in their toxic effects or in the way they were handled by the body. It was chosen mainly because in the absence of any information to the contrary it was easy to assume that the toxicity of inhaled uranium, about which nothing was known, was comparable with that of lead, about which a great deal was known. As this air concentration had been attained in the lead industry, it seemed likely that it would be attainable in the uranium industry. This decision has been described by Hodge (1949) who pointed out that at this early stage the radioactive hazard from inhaled uranium seemed less important than the chemical toxicity. (Spoor and Hursh 1973, p. 244)

The primary site of the ideas was the Manhattan Project at the University of Rochester, but the decision involved the top management of the Medical Section of the Manhattan Project as well, e.g., Drs. Stafford Warren and Hymer Friedell (see previous chapters). The reference to Hodge (1949) in the above quotation is given in both chapters 2 and 9 (Voegtlin and Hodge).

As the large animal experiments at Rochester progressed (see chapter 9), it was obvious that soluble and insoluble compounds had to be dealt with separately. It appeared that chemical toxicity to the kidney would be the controlling injury for soluble compounds for the following reasons:

1. The amount of natural uranium deposited in lung, kidney, or bone would never constitute a radiological hazard. It was removed too rapidly.
2. The kidney injury is an extremely sensitive indicator of chemical toxicity, and an amount of soluble uranium in the atmosphere that fails to produce any kidney injury is a physiologically safe concentration. (Paraphrased from Spoor and Hursh 1973)

As detailed by Spoor and Hursh, the inhalation experiments at Rochester with dogs, rats, rabbits, and guinea pigs exposed for one year to air concentrations of soluble uranium varying from 40 to 2,000 $\mu\text{g U}/\text{m}^3$ were used to develop a recommendation. A safe level of 50 $\mu\text{g}/\text{m}^3$ was recommended tentatively as the (MPC)_a for soluble uranium. A useful summary of the data employed is given by Voegtlin and Hodge (1953, p. 1660) (cited in chapters 2 and 9).^(a)

To arrive at these summary figures, the very large effort detailed in chapter 9 was brought to bear. In the words again of Spoor and Hursh:

The Rochester experiments were conducted on a scale that is probably unequalled in the history of toxicology. The aim of the project was not in the first instance to provide one or two (MPC)_a values; it was rather to complete a comprehensive study, using different animal species, of the toxicology of several uranium compounds.

(a) It is a sad commentary on the lack of public understanding of the stresses of the war years and of the reasons for adopting a clearly empirical interim standard based on lead that over thirty years later this reduction from 150 $\mu\text{g}/\text{m}^3$ to 50 $\mu\text{g}/\text{m}^3$ was made the occasion by members of the Rochester press to castigate Dr. Hodge, who was the senior investigator, for having "overexposed" hundreds of MED workers. The reasoning was that all who had worked under the original higher level had been overexposed and should have been so informed. In view of the tightness of security in those days, it is hard to visualize how any such message could have been conveyed. Nor is there any reason to think a majority of the workers had actually been exposed to the original interim level, despite knowledge that some processes were performed relatively "dirty." Furthermore, the standards later went back up. Would the castigators be better satisfied if the scientists had not conscientiously reduced the level on the basis of the new information?

The task of marshalling and interpreting all of the data obtained presented a problem of considerable complexity. The results were published in detail, and the methods of interpretation explained in full. It is clear from the reports that no statistical methods were available, or conceivable, by which such a wide range of experimental data could be reduced to two (MPC)_a values. The authors explained that "decisions were hard to make in some instances because it was difficult to fit large masses of data that were occasionally perplexing or even conflicting into the four arbitrary classifications of (1) safe, (2) MAC, (3) borderline, and (4) toxic for the response levels."

(Spoor and Hursh 1973, p. 245)

Typical graphs embodying work on soluble uranium appear as figure 16.2A and B (taken from Voegtlin and Hodge 1953, p. 2207); there were numerous others for both soluble and insoluble compounds. This was the classic toxicologic approach. Nevertheless, the conclusions were regarded as tentative since there was full recognition of the possible differences between animals and humans.

A computational approach analogous to that used for radiation was applied to derivation of a standard for uranium in man. This was based upon an MPC of soluble natural uranium in kidney and the concept of a threshold chemical effect. As Spoor and Hursh explained, the value of 3 $\mu\text{g U/g}$ kidney was arrived at by a committee judgment based on the Rochester data.^(a)

The early approach to a standard for *insoluble* uranium was much less direct than that for soluble uranium. However, the early derivations were not woven into the computational system to be discussed in section IV and will therefore be taken up here. Basically it was decided that the long residence time of inhaled insoluble uranium in tissues, such as lung and pulmonary lymph nodes, greatly reduced the chance of chemical toxicity to kidney. It was concluded that here the potential radiation hazard would control. A calculation by William F. Bale at Rochester was made to determine the concentration of natural uranium that would deliver the then-accepted maximum permissible dose rate of 0.045 rem/day to the tissue. The result was 24 $\mu\text{g/g}$ of fresh tissue. Using the lung deposition figures from the one-year inhalation experiments with dogs and rats,^(b) it was calculated that exposure to 100 $\mu\text{g U/m}^3$ of air would result in a lung tissue content of 24 $\mu\text{g/g}$, the maximum allowable amount.

There were thus two limits, 50 $\mu\text{gm/m}^3$ for soluble uranium and 100 $\mu\text{g/m}^3$ for insoluble uranium.

It should be noted that neither this nor most later experiments with insoluble uranium produced evidence of radiation damage to the tissue. Indeed, as we saw in chapters 2 and 9, it took an eleven-year experiment of heroic proportions to finally produce, at levels far above the MPCs, clear-cut radiation damage from natural uranium. Thus, the criteria for soluble and insoluble uranium were basically different. The one involving chemical toxicity was derived from finding effects and assigning a threshold concentration. That involving radiation effects was based on an assumption regarding the permissible dose rate and a

(a) As we will see later, other data, such as half-time in the kidney, transfer functions, etc., were needed also and had to be gleaned largely from the animal data. Hursh (1975) takes the view that the application of the approach used for radiation to chemical effects was of questionable validity at best.

(b) Note that the lung deposition was determined from the experiments, not from a model as was done later.

FIGURE 16.2A. (Right) Graphical presentation of responses to UF_6 and UO_2F_2 exposures by inhalation. (Redrawn from Voegtlin and Hodge 1953, p. 2207.)

FIGURE 16.2B. (Left) Graphical presentation of responses to $\text{UO}_2(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$ exposure by inhalation. (Redrawn from Voegtlin and Hodge 1953, p. 2220.)

calculation of the concentration expected to produce that dose rate in tissue using parameters developed from animal experiments. There followed a long series of revisions of both standards, all of them within an order of magnitude of each other, but ranging from $25 \mu\text{g}/\text{m}^3$ to $200 \mu\text{g}/\text{m}^3$. As Spoor and Hursh described, each revision was based on some new point of view or new data and ideas coming from the multitude of meetings and organizations we will review presently. The controlling process shuttled back and forth between chemical toxicity and radiation effects.

Probably the last of the direct determinations for uranium came from the American Council of Governmental Industrial Hygienists (ACGIH). They used the standard industrial hygiene approach of setting levels on the basis of experience in the work place. Whereas during the war some exposures to uranium were high enough to develop a considerable crop of cells and albumin in the urine of the workers, adherence to the recommended standards had appeared to bring these effects under reasonable control. In 1957, the ACGIH recommended limits of $50 \mu\text{g}/\text{m}^3$ for soluble uranium in air and $250 \mu\text{g}/\text{m}^3$ for insoluble uranium in air. These values were related explicitly to the Rochester experiments (Spoor and Hursh 1973) but included also some consideration of in-plant experiences (see, for example, several reports from industry at the 1975 ERDA Conference cited earlier, and also Hursh 1975). In 1968, the ACGIH changed their recommended limit to $200 \mu\text{gU}/\text{m}^3$ of air for *both* soluble and insoluble compounds of uranium. This was based on the fact that twenty-five years of industrial experience had failed to show "any definite association between exposure to higher levels of airborne uranium and injury either to the kidney or to the blood" (Spoor and Hursh 1973, p. 249).

This proposed increase raised some hackles in the radiation protection community, even before it was promulgated (Morgan to Stokinger 1967a; Stokinger to Schulte 1967, with copy to Morgan). Morgan's argument was that the measurement data were not very quantitative, and furthermore "some types of damage with which we are concerned may make their appearance long after exposure and the damage may be expressed in forms difficult to recognize, e.g., damaged kidneys that are more susceptible to certain diseases" (Morgan 1967a).^(a)

The members of the Threshold Limit Committee were nurtured in the conventional industrial hygiene approach (e.g., H. Stokinger, J. Quigley from National Lead, et al.), and the ACGIH figure has prevailed, except where limited by the U.S. Code of Federal Regulations, Title 10, on atomic energy.

Unfortunately, epidemiologic studies of uranium workers had been from crude to nonexistent. Only in the 1980s did useful analyses begin to appear. We will review these in section VII. Hence, there was little except metabolic data from humans to contribute further to the direct determination of uranium standards.

It may be noted that even today (1987) the choice of a proper basis for uranium standards, chemical toxicity or radiation effects, continues to shuttle back and forth. It is not a simple story.

(a) It is interesting to note that the levels derived by ICRP (see section IV) in 1958 corresponded to $210 \mu\text{g}/\text{m}^3$ for soluble uranium, based on chemical toxicity, and $180 \mu\text{g}/\text{m}^3$ for insoluble uranium, based on a limiting dose rate to lung of 15 rem per year. These levels were reiterated in 1962.

E. Standards for Plutonium

Standards were needed for plutonium, principally ^{238}Pu and ^{239}Pu , almost as soon as these elements appeared on the scene. Thus, the situation resembled that for uranium, only it was much worse. At least uranium had been around for many years and something was known about its potential biological effects (Hodge 1973). Plutonium was completely new. There was no backlog of experience to foster even a guess. Yet, as described in some detail in chapter 7, progression from microgram to kilogram quantities was to be accomplished over an incredibly short interval. Therefore, the only recourse for setting standards was initially by analogy, much as was done with uranium.

The story of how quickly we learned about plutonium is told in chapter 7. The concern for setting standards meant that almost every piece of new biological information was snapped up avidly for possible incorporation into a viable standard. During the days of World War II, the Metallurgical Laboratory, Los Alamos, Hanford, and Rochester were the centers for these activities. The early report literature, quoted in part in earlier chapters and in the book by Friedell (1983), traces the steps well. We are blessed with a superb summary of most of the important steps in a review prepared by Langham and Healy at Los Alamos (1973) for the same volume, *Uranium, Plutonium, Transplutonic Elements*, in which the Hursh and Spoor review on uranium appeared.

We will review here primarily the early stages of standard setting for plutonium since these relied largely on the direct approach. Most later developments involved a mixture of directly obtained toxicologic information and the calculation of radiation dose and will be saved for section IV.

Let it be emphasized that there was at the outset, and is to this day, no direct information on effects of plutonium in humans. Therefore, neither the direct observational approach applied to radium nor the industrial hygiene approach applied to radon and to some extent to uranium were available for plutonium. Instead, a series of inferences had to be made.

As soon as it was clear from the very early experiments of Joe Hamilton at Berkeley that plutonium deposited preferentially in bone, researchers sought to develop a standard for it based on ^{226}Ra . The first attempt was on the basis of the respective half-lives, i.e., 1,600 yr for radium versus 24,500 yr for ^{239}Pu . On this basis, it could be predicted that plutonium would be about 0.07 or one-fifteenth as toxic as radium. But this neglected the difference in energies. The average energy of the plutonium alpha particle is 5.15 MeV. The energy from ^{226}Ra is considerably higher, because of the energies of the several decay products. Assuming 50% retention of the radon produced in situ from the radium in humans (an old figure; it is now taken as 30%), the total energy from ^{226}Ra down to ^{210}Pb (radium-D, twenty-two year half-life), is about 14.4 MeV (alpha energy only). A more sophisticated calculation, and evidently one of the first (Langham and Healy 1973) was the following, based on the 0.1 μg limit for radium:

$$\begin{array}{ccccccc} \text{Maximum Permissible} & & \text{Maximum Permissible} & & \text{Ratio of} & & \text{Ratio of} \\ \text{Body Burden for} & = & \text{Radium Burden} & \times & \text{Half-lives} & \times & \text{Energies} \\ \text{Plutonium} & & & & \text{Pu/Ra} & & \text{Ra/Pu} \\ \text{or MPBB for Pu} = 0.1 \mu\text{g} & \times & \frac{24,500}{1,600} & \left[\frac{4.8}{5.15} + \frac{0.5(5.5)}{5.15} + \frac{0.5(6.0)}{5.15} + \frac{0.5(7.7)}{5.15} \right] \\ & & & & \text{}^{(226}\text{Ra)} & \text{}^{(222}\text{Rn)} & \text{}^{(218}\text{Po)} & \text{}^{(214}\text{Po)} \end{array}$$

$$\therefore \text{MPBB Pu} = 4.3 \mu\text{g} \approx 5 \mu\text{g}.$$

Before this standard could be promulgated, the autoradiographic evidence from the Berkeley group began to come in. It was apparent that plutonium deposited in bone quite differently from radium. As shown in figures 7.9, 7.10, and 7.11 of chapter 7, plutonium eschewed mineral bone and concentrated more in what was then called the "organic matrix." We can now pinpoint the localization as primarily on the endosteal surfaces of bone. Since these were already known to be intimately associated with bone growth, the early workers reasoned that alpha-particle irradiation might be more damaging in this area than if it were distributed largely in mineralized bone, as was ^{226}Ra . This raised a red flag regarding the relative toxicity of plutonium, even though it did not give quantitative information.

As a result of this, the first generally adopted standards within the MED appended some safety factors to the $5\text{ }\mu\text{g}$ possible level. The factor was taken as ten by the Hanford Operations people and five for the balance of the MED operations. The resulting maximum allowable body burdens were $1.0\text{ }\mu\text{g}$ ($0.06\text{ }\mu\text{Ci}$) for the MED generally and $0.5\text{ }\mu\text{g}$ ($0.03\text{ }\mu\text{Ci}$) for Hanford. These decisions were made primarily by Metallurgical Project people and at Hanford. As we saw in chapter 7, the discoverer of plutonium, Glenn Seaborg, was very active in assuring that adequate safety standards were instituted.

The first values for an air concentration level of plutonium were also derived by the direct method. As Langham and Healy (1973) described, S. K. Allison, director of the Metallurgical Laboratory in Chicago, wrote in March 1944 to J. R. Oppenheimer, director of Site Y (Los Alamos) that air containing $2 \times 10^{-15}\text{ g/cm}^3$ of plutonium ($1.2 \times 10^{-10}\text{ }\mu\text{Ci/cm}^3$) would be dangerous if exposure occurred for 48 hr/wk for two years. This was based on assuming that $50\text{ }\mu\text{g}$ of plutonium in the skeleton was equivalent in energy deposition to $1\text{ }\mu\text{g}$ of radium and that, since lungs weighed about one-tenth as much as skeleton, the equivalently dangerous level in the lungs would likewise be one-tenth of $50\text{ }\mu\text{g}$. Allison assumed a breathing rate of 10 l/min and evidently made no allowance for elimination from the lung. On this basis, the air concentration was:

$$\frac{5 \times 10^{-6}\text{ g}}{10^4\text{ cm}^3/\text{min} \times 2.8 \times 10^5\text{ min in 2 yr}} = \sim 2 \times 10^{-15}\text{ g/cm}^3$$

Note this was equated to $1\text{ }\mu\text{g}$ of radium, not $0.1\text{ }\mu\text{g}$ and thus was regarded as *dangerous*, not an allowable level.

Meanwhile, the animal experiments comparing plutonium, polonium and radium described in detail in chapters 7 and 8 were proceeding. We will continue the story by a quote from Stannard's review written in 1980 and published in 1981:

By 1947 the experimental programs began to bear fruit on all fronts. Contrary to the simple calculations it turned out that ^{239}Pu was more toxic than ^{226}Ra .

This was the beginning. By 1948-49 the Chicago work by Miriam Finkel, Austin Brues *et al.*, suggested a toxicity ratio of plutonium to radium of approx. 15 to 1. This would yield a permissible burden of 5/15 or $0.3\text{ }\mu\text{g}$. These figures went into the first TriPartite (U.S.A., U.K., Canada) Permissible Doses Conference in 1949 and a further reduction was made. The Conference adopted *protem* a maximum

plutonium body burden of $0.1 \mu\text{g}$ ($0.006 \mu\text{Ci}$). (a) This literal reaction to the toxicity ratio was clearly an over-reaction and the final version of the Conference report, done by the Canadians, lists $0.5 \mu\text{g}$ ($0.03 \mu\text{Ci}$). The literal reaction left out several important considerations. These were:

- The Chicago studies were based on injected dose. Pu retention in the rodent is 75% while radium retention is only 25%.
- The retention of radon differs between rodent and man. It is 15-20% in the rodent vs about 50% in man . . .

As described by Langham and Healy this situation led to an important meeting called in Washington in January 1950 by the late Dr. Shields Warren who was then Director of the new Division of Biology and Medicine of the Atomic Energy Commission. It is reported that Wright Langham gave a 2 hr presentation on the reasons the Chalk River values should not be adopted. He was followed by Austin Brues who presented the following, now classical relationship

$$1 \mu\text{Ci Ra} = \left[\frac{1}{15} \times \frac{0.75}{0.25} \frac{4.8 + 0.5 (5.5 + 6.0 + 7.7)}{4.8 + 0.15 (5.5 + 6.0 + 7.7)} \right]$$

The toxicity ratio in rodents	Retention ratio Pu/Ra in rodent	Energy ratios man/rodent- MeV modified by radon retention
--	--	---

$$= 0.4 \mu\text{Ci} (6 \mu\text{g}) \text{ Pu. (b)}$$

As Langham remarks, with perhaps too much modesty, it took Brues 5 min to make this presentation. If he had gone first the meeting could have been over in 10 min! My own view is that the numbers would probably have not fallen on such fertile soil if the need for a different view had not been emphasized by Langham. Besides, they could not have borne to come all the way to Washington and talk for only 10 min.

Dr. Warren is reported to have summarized the meeting with the suggestion that $0.5 \mu\text{g}$ ($0.03 \mu\text{Ci}$) could be viewed as equivalent to $0.1 \mu\text{g}$ ($0.1 \mu\text{Ci}$) of ^{226}Ra the

- (a) The reaction to this proposal at Los Alamos was violent. Langham, Harriet Hardy, who was there from MIT as a consultant, and others were certain that the laboratory could not possibly meet the stringent air concentration standards that a permissible body burden of $0.006 \mu\text{Ci}$ would entail. If this standard were adopted and enforced, the laboratory would have to shut down. In a very depressed mood, Wright Langham telephoned Robley Evans for advice and for help in finding a way out. He was convinced that the new level was wrong on biological grounds, not simply because it might shut down a major facility. To bolster Langham's morale, Evans suggested (Evans 1983) that he take a Filter Queen air sampler out into the woods of the mountains surrounding Los Alamos and compare the alpha activities there with those in the laboratory air. To Langham's delight, the readings from the pure, healthful, bracing mountain air were consistently and significantly higher than most of the laboratory air samples! There are, of course, some pitfalls in this because of the relative contributions of radon and its daughters in the two environments. But it served to revive Langham's spirits and give a holding argument while the complete story unfolded.
- (b) Note this is equivalent to $1 \mu\text{Ci}$ of radium. The "tolerance" value would, of course, be one tenth of this, or $0.04 \mu\text{Ci}$ ($0.6 \mu\text{g}$).

accepted maximum allowable body burden and that AEC operations could proceed on that basis.

In the ICRP-NCRP reports of 1954 and 1959 the figure is given as $0.04 \mu\text{Ci}$ which agrees with the derivation in the last equation with introduction of $0.1 \mu\text{Ci } ^{226}\text{Ra}$. (Stannard 1981 with slight modification and footnotes added)

The figure, $0.04 \mu\text{Ci}$ body burden of ^{239}Pu stood for many years. As described in chapter 8, the long-term experiments with beagles did not materially alter the picture. They confirmed and strengthened the validity of the toxicity ratios used. However, the system changed considerably from the direct to the computational approach. We will save further details, therefore, for that section.

An interesting variant of the direct approach to setting a standard for plutonium is found in calculations regarding a single intake. This might apply to a possible release from a fast reactor accident. The work was contained first in a Master of Science thesis prepared by H. G. Gavankar in the Department of Nuclear Engineering at the University of California, Berkeley under the general direction of Thomas Pigford and in collaboration with Patricia Durbin (Gavankar 1972). It was later presented at a topical meeting on Fast Breeder Reactor Safety held by the American Nuclear Society (ANS) in April 1974 (Gavankar, Durbin, and Pigford 1974). This came long after the computational approach had taken over. However, it utilized tumor risks estimated directly from the beagle dog experiments and related them to organ burdens. The abstract of the ANS paper tells the story:

This paper presents a method of assessing emergency radiation risks from a single inhalation of a $^{239}\text{PuO}_2$ aerosol. The ICRP Lung Model was used to calculate organ burdens and doses resulting from a single intake. Tumor risks have been estimated from experiments in which Beagle dogs inhaled $^{239}\text{PuO}_2$ particles (Thompson et al. 1972) or were injected with ^{239}Pu citrate (Mays et al. 1970); tumor risks could be related directly to organ burdens. We extrapolated lifetime tumor risks and expressed as (a) tumor risk/person/rem of organ dose accumulated over 50 years, and (b) tumor risk/person/nCi of organ burden (initial deposit in lung or 50-yr accumulated burden in bone and liver).

For purposes of illustration a "reference risk" was adopted—the published cancer mortality risk associated with the emergency dose guideline in existing reactor siting criteria (25 rem whole-body exposure in 2 hr). A comparison of tumor risks with the reference risk showed that 50-yr accumulated doses of 10 rem, 25 rem and 75 rem in the lung, liver and bone, respectively, were separately "risk-equivalent" to the reference risk. On a "total" risk basis (summation of independent incidences of tumors of lung, liver and bone from the same inhalation intake) the risk-equivalent intake varies with the particle size. For an ideal $0.5 \mu\text{m}$ AMAD aerosol, the risk-equivalent intake, about 19 nCi, results in 50-yr accumulated doses of about 7 rem, 8 rem, and 3 rem to the lung, liver and bone, respectively. Smaller particles pose greater total tumor risk; the risk-equivalent intakes of aerosols ranging from 0.05 to $3.0 \mu\text{m}$ AMAD were shown to be within the range, 9 to 36 nCi. (Abstract from Gavankar, Durbin, and Pigford 1974, references not reproduced.)

F. Other Radionuclides

We have now considered the principal instances where the direct approach to deriving a standard from effects data has been overtly and seriously applied. Somewhat less extensive and semidirect derivations can be cited for ^{224}Ra and ^{232}Th in Thorotrast.

1. Radium-224

In chapter 1, we reviewed the saga of the use of ^{224}Ra (ThX, half-life 3.64 days) as a therapeutic nostrum in German hospitals and a country doctor's practice over the period 1944 to 1951. Over two thousand patients were involved. Amounts given were ample to produce effects (40 to 5,000 μCi per person). However, the generation of effects required the usual long latent period. A standard was already in place by the time Spiess and Mays, at Utah and in Germany (see chapter 1), began their epidemiologic study. Thus, the information has been more valuable for validation than for setting of a standard. It may be useful in the future since ^{224}Ra deposits on bone surfaces initially, like plutonium, and, because of its short half-life, expends most of its alpha energy thereon. Thus it could, to a degree, be a useful surrogate for plutonium effects in humans.

Spiess and Mays (1973), and Mays and Spiess (1984) did derive figures from the effects data to quantitate the effectiveness of ^{224}Ra in juveniles and adults (see chapter 1). They used these to support the thesis that protraction of dose *increased* the effectiveness of alpha-particle radiation. This is, of course, the opposite of the usual effect of protraction seen with low linear energy transfer (LET) radiations. This phenomenon found its way into the third BEIR report (BEIR 1980, see especially pp. 411-414).

While no new or modified standards have resulted to date, it seems likely that these phenomena will be considered in future revisions of standards for short-lived radium isotopes.

2. Thorium-232 as Thorotrast

In chapter 4, we reviewed the accumulating biological data on the radiobiology of thorium isotopes. The largest exposed population of humans consists of patients who received a colloidal preparation of ^{232}Th with some added adjuvants as a radiocontrast medium called "Thorotrast." Here the problems are appearing largely as liver cancer. There is no doubt that the story has served to push the liver into a position of much greater prominence in consideration of radiation standards than was the case earlier. (Many other radionuclides, including alpha-emitting actinides, also deposit in liver to a considerable extent, as we have seen.) However, the dosimetry of Thorotrast is most difficult, and, until some current experiments are completed, the possibility of a chemically toxic component cannot be eliminated.^(a) Therefore, the data, although extensive, have not had much use to date for direct determination of standards. However, like the data for ^{222}Ra , they may play a part in the future, especially in establishing direct estimates of risks. An epidemiologic study of thorium dioxide in gas mantle manufacturing plants may also contribute in the future (Stehney et al. 1980; also Stannard 1983).

G. The Approach of the Federal Radiation Council

The plan and work of the FRC was taken up in section II. Its approach was enough like those described in this section to warrant identification here.

The work of the FRC began long after the computational approach had taken over for the general development of standards (section IV). Nevertheless, they

(a) These experiments at Utah have now reached the stage where chemical toxicity of the Thorotrast seems unlikely, but the first publications are not yet ready.

chose to analyze the pertinent information for important radionuclides on an individual basis. Their recommendations were thus idiosyncratic to a degree for each situation analyzed, although, unlike the very early direct approaches, they were done within a general framework of acceptable radiation doses and dose rates.

The radionuclides taken up by the FRC were primarily those in fallout from nuclear weapons testing considered first generically and then with specific consideration of ^{89}Sr , ^{90}Sr , and ^{137}Cs . There was also an in-depth review of the pathological effects of thyroid irradiation and thus, of course, the information on ^{131}I . Finally, the FRC worked in some depth on radon and its daughters, as discussed in chapter 3. Their operations were unique and original and their approach a mixture of the direct and the computational modes.

IV. The Computational Approach

A. Development

The process of nuclear fission added immeasurably to the number of radionuclides that needed consideration not only in terms of their behavior and effects (see chapters 6 and 7), but in terms of standard setting. Even during the war years, methods were worked out for calculating the radiation dose delivered to tissues by a variety of deposited radionuclides. These methods remained within the classified literature until the end of the war. The principles are clearly set forth in two early publications that are now to be regarded as classics and in one Metallurgical Laboratory report. The first publication, developed by Karl Z. Morgan and published in 1947 was based on a Met Lab report of 1945 (Morgan 1945), which was never published in full, although it was proposed for the National Nuclear Energy Series (NNES). It gave basic principles, general methods for calculation, and data for seventeen radioisotopes in different forms. This had obviously grown out of several years of work in the MED laboratories. The published paper was reproduced as a landmark paper in the Health Physics Society's Silver Anniversary volume (Morgan 1947 and 1980) and is thus easily available now.

A similar, but somewhat more generic report came from Waldo Cohn, who also worked in the Metallurgical Project at Clinton Laboratories (Cohn 1948). It too was reproduced in the cited Silver Anniversary volume as a landmark paper (Cohn 1980). It is not clear to what extent, if any, these two contributions represented interactions between the authors, nor is it important to establish this point. Both were at Clinton Laboratories for considerable periods, but Morgan began in the original Met Lab structure, even before the Clinton Laboratories were operational. Both used basic principles that had to underlie much of the MED biomedical consideration of radioactive materials.

The distinctive value of these is the development of a new and general approach. Obviously, there could be no retrospective analyses of experience in man for the hundreds of radionuclides that appeared *de novo* in nuclear fission. Even the data from animals had many gaps and, in terms of effects, concerned primarily relatively high doses (chapters 6 and 7). Generic analyses based on behavior of the stable elements helped. However, there was essentially no way to apply the direct approach described in section III. Yet, those concerned with standards wished to propose limits for all possible radionuclides as soon as possible. The answer was the development of a general system by which doses

could be calculated and related to an accepted "tolerance dose" or "maximum permissible dose." Secondary standards for intake or for concentrations in air or water could then be derived from these.^(a) Both the paper by Morgan and the one by Cohn are strong on use of first principles, which formed the basis for this system.

The Tri-Partite Conferences held in 1949, 1950, and 1953 (section II A.4) sparked the development of the computational system. By the completion of the third conference, the framework of an acceptable system for calculating standards had been developed, using the principles set out in the reports cited above, and earlier in the laboratories of the MED and also abroad. (The participants in these conferences are listed in section II.) Each individual and each laboratory contributed ideas and, once the plan had been agreed upon, each contributed important information concerning the behavior of individual radioisotopes in humans and animals.

The results of the three Tri-Partite Conferences fed in turn into the step-wise development of reports and tabulations by the internal emitter committees of the NCRP and ICRP (see section II).

There was first a statement from ICRP (1951) giving preliminary figures for maximum permissible levels and some of the data used for the most important radionuclides (^{226}Ra , ^{239}Pu , ^{89}Sr , and ^{90}Sr plus ^{90}Y , natural uranium, ^{210}Po , tritium, ^{14}C , ^{24}Na , ^{32}P , ^{60}Co , and ^{131}I). The report gave the background for each radionuclide.^(b)

Next came a compendium giving the normal behavior in the human body of all elements through $Z = 98$, plus data on limits for eighty-nine radioisotopes (ICRP 1955, NCRP 1953).

This major first phase culminated in comprehensive reports in 1959, which included approximately 215 radionuclides and 355 MPC values (ICRP 1959, NCRP 1959).

At this time, the committees of NCRP and of ICRP working on MPCs of radioisotopes were both chaired by Karl Morgan, and they worked closely together. Indeed, their reports appeared almost simultaneously. However, they were different. The ICRP's 1959 report gave details of the equations and methods of calculation along with tables of maximum permissible body burdens, critical organs, MPCs in air and water, and some of the biological input data. The NCRP's 1959 report, published as an NBS Handbook, gave all of the tables and some correlated information, but did not expand on the calculational methodology. Neither report gave full documentation of the origin of the input data.^(c) These were reserved for a special volume of the journal, *Health Physics*, which contains the report plus a bibliography for biological data, a bibliography for mathematical and physical data, and also indexes by authors and by elements, a monumental task (*Health Physics* 1960). While the reports are still quite generally available (they have been used for many years), this special volume of

(a) Some details of the mechanics of internal dose calculations are given in the chapter on Nuclear Medicine (chapter 20). The present discussion concentrates on the applications of the research data.

(b) Since this report was also published as a supplement to an NBS Handbook, we can be sure that both NCRP and ICRP participated, even though it is officially a report of the ICRP.

(c) The reports of the earlier fifties were rather completely documented. By the 1959 reports, the documentation was too extensive for a "handbook."

Health Physics is not so generally available. Yet, anyone wishing to trace in-depth the origin of any given figure in the ICRP/NCRP reports of 1959 must depend upon this source. It should be sequestered as a national treasure.

The members of the two committees that produced these invaluable compendia were:

National Committee on Radiation Protection and Measurements:^(a) Committee-2

K. Z. Morgan, Oak Ridge, Chairman
A. M. Brues, Argonne
P. W. Durbin, University of California, Berkeley
C. Failla, Columbia University
J. W. Healy, Hanford
J. B. Hursh, Rochester
L. D. Marinelli, Argonne
W. S. Snyder, University of Tennessee
S. Warren, Harvard (New England Deaconess Hospital)

For NBS Handbook 52 (NCRP Report 11) J. G. Hamilton, University of California, Berkeley; H. M. Parker, Hanford; and J. E. Rose, Chicago, also served.

International Commission on Radiological Protection:^(b) Committee II

K. Z. Morgan, U.S., Oak Ridge, Chairman
W. Binks, U.K.
A. M. Brues, U.S., Argonne
W. H. Langham, U.S., Los Alamos
L. D. Marinelli, U.S., Argonne
W. G. Marley, U.K.
M. K. Nakaidzumi, Japan
G. J. Neary, U.K.
M. N. Pobedinski, USSR
E. E. Pochin, U.K.
C. G. Stewart, Canada

Much of the detailed work for both NCRP and ICRP was carried out by the Internal Dosimetry Section of the Oak Ridge National Laboratory, e.g., Mary Jane Cook for collection and development of the biological data; Mary Rose Ford for physical data and computations; Janet Kohn and James Muir for effective energies and gastrointestinal tract values; all under the supervision of Dr. Walter S. Snyder.

B. The Basic System and Its Research Background^(c)

It is unnecessary here to describe mechanical details of the dose calculation approach adopted since they have been well documented in easily available sources and will be presented in chapter 20.^(d) We do need to set out briefly the basic assumptions made, the kind of data required, and the ways in which

(a) Now National Council on Radiation Protection and Measurements (section II).

(b) This represents the composition at the time the report was completed. In the period 1953 to 1956, A. J. Cipriani, Canada, served instead of C. G. Stewart.

(c) Since we are emphasizing history, we will concentrate on the system in operation for several decades and touch rather lightly on current practices. The uses of research data are not very different in the current system, only expanded.

(d) If the reader cannot wait for chapter 20, the excellent chapter by Snyder in the Morgan and Turner textbook is recommended (Snyder 1967 and 1973).

the research in the biomedical community reviewed in this book has contributed to it. We need also to review some of the research done specifically for the system.

Originally the system was applied primarily to occupational exposure. The following plan was adopted:

1. Intake occurred either continuously for a full 168-hr week or continuously over a 40-hr work-week.
2. Intake limits were devised so that the dose rate in a critical organ or the whole body would never exceed the stated maximum permissible dose rate during a working lifetime, assumed to be fifty years.^(a) Except for those radionuclides that deposit in bone, the maximum permissible dose rate was based on experience with external radiation sources.
3. A quantity known as the "effective absorbed energy," which considered both the physical properties of the isotope (see chapter 20) and the relative biological effectiveness, later called the "Quality Factor," of the radiation type emitted by each radionuclide, was calculated for each organ and the body as a whole.
4. Information on the distribution of each radionuclide to body tissues was assembled. The accumulation of dose to each organ or tissue and the associated maximum permissible body content was calculated from this information. Of these, the organ or tissue resulting in the most restrictive air and water concentrations and the lowest permissible body burden was usually selected as the "critical organ." Only when this selection process pinpointed a tissue of obvious radioresistance or an organ of little biological significance and there were other tissues with nearly the same concentrations would the "critical organ" be other than the one with the highest concentration of radionuclide. With isotopes of more or less uniform distribution, the whole body became the critical organ. In many instances with poorly absorbed substances the gastrointestinal tract might be critical, at least under the conditions of more or less constant intake.
5. The tabulations usually showed the maximum permissible body burden and derived figures for a number of organs. The more restrictive ones were placed in bold type. Behind the scenes, many other organs were also calculated, indeed, nearly all except for radionuclides with very specific localization. However, many were not shown in the tables since they were beyond any possibility of being critical.
6. Derived limits (the real operational limits called maximum permissible concentrations) were calculated for radionuclides in air (MPC_a) and water (MPC_w) for intake over a normal work week and also for continuous intake. To derive these, many assumptions had to be made. These included the normal fluid intake by workers, the behavior of various segments of the gastrointestinal tract in terms of times, masses, etc., and the behavior of inhaled materials. These necessitated the development of many general biological models (see section VI) as well as the data for specific isotopes.

What did the internal emitter research data contribute to this operation? A great deal, as shown below:

1. The storehouse of information on tissue distribution of radionuclides was used to calculate organ doses and to derive the critical organ. At the time the

(a) In some of the earlier calculations, the dose to seventy years was used.

effort started, the information we have summarized in chapters 6 and 7 was the primary source. This was a good start, but led to the following statement in the introduction to the ICRP's 1955 report:

Ideally, one would prefer to select maximum permissible body burdens and maximum permissible concentration values that are based on observations on humans who have consumed the particular radioactive material under the conditions and over a period of time approximating those set forth as being applicable to the maximum permissible values selected. Only in the case of radium, however, does one have an accumulation of human experience over a period of years that is suitable to serve as a basis of selection of these values. In a few cases the chemical behavior of other elements is sufficiently similar to that of radium so that comparisons with radium may serve as a basis of choice of maximum permissible values. Usually, however, human data are lacking completely for a particular radioisotope and in such cases data from limited animal experiments must be extrapolated to man. Sometimes even animal data are not available and in such cases estimates are made from a comparison with elements having similar chemical properties and/or from an investigation of the body retention, distribution and elimination of stable isotopes of the radio-element under consideration.

(ICRP 1955, p. 23)

Every new experimental finding of the ensuing years (chapters 8, 9, and 10) got plugged into the system avidly.

2. Information was needed on the retention kinetics of each radionuclide, i.e., not only where did it go, but how long did it stay, and what was the time course of its release? The results of the internal emitter research were used for calculation of the biological and effective half-lives (see chapter 20) for each radionuclide.
3. Numbers were needed for various transfer functions such as:
 - a. fraction of radionuclide passing from gastrointestinal tract to blood;
 - b. fraction passing from blood to critical body organ;
 - c. fraction in critical organ to that in the total body;
 - d. fraction of that taken into the body that is retained in the critical organ.

Each of these received a symbol in the formulations and was derived as best possible from the research data. The steady flow of new work (chapter 8) contributed enormously to the ongoing effort. Yet, a majority of the references in volume 3 of *Health Physics* (1960), where the references for ICRP Publication 2 were brought together, are not much later than the middle 1950s, and many go back to the 1930s, particularly those concerning the behavior of the stable isotopes of certain elements.

C. Bone Seekers

An entirely different approach was used in the first computational approach for those radionuclides that deposited primarily in bone. The reliability of the standard derived for ^{226}Ra (section III) was fully recognized. Instead of applying the maximum permissible dose rate used for other substances, the system for the bone seekers used the permissible body burden of ^{226}Ra as a bench mark (i.e., $0.1\ \mu\text{Ci}$ or μgm). Other bone seekers were related to it by a comparison of the energy deposited in bone by the particular radionuclide as compared to that deposited by $0.1\ \mu\text{Ci}$ of ^{226}Ra and a fraction of its daughter products. The relationship used is shown in note 1 at the end of this chapter.

To accommodate the greater effectiveness of those bone seekers that deposited on bone surfaces, a factor, n , was introduced into the formula for effective energy.^(a) This factor n (originally written as the Greek letter, “eta,” but soon called the n factor) was taken numerically to equal one if the parent element of the chain was an isotope of radium or if the original energy component was x-or gamma-radiation. It was taken as five in all other cases. It was called the “relative damage factor” in 1959. Because the difference in damage between these radionuclides was thought to be resident in the details of their distribution pattern within bone, discussed many times in this book, it was sometimes known also as the “distribution factor.”

This system obviously wove in some of the features of the empirical toxicity ratio discussed in connection with plutonium in section III E. However, it was still a computational approach. It allowed for only two relative toxicity ratios, one or five. The reason NCRP/ICRP did not use toxicity ratios directly and to the full is addressed in ICRP 1959: “When the necessary data are available, the maximum permissible body burden, q , of a radionuclide may be determined by a comparative study of the clinical findings and biological damage produced by various quantities of ^{226}Ra and the radionuclide under study. Studies of chronic exposure—a few of which have been started—should furnish the most direct and reliable values of q . Until these studies have been completed it may be necessary to continue to determine values of q by a direct comparison of the energy deposited in bone. . .” (ICRP 1959, p. 13, reference in text omitted).

What was not said was that the toxicity ratios available then involved only experiments on short-lived rodents, and there was concern that they might not apply to humans. They were, as we saw in chapters 7 and 8, truly chronic experiments for rodents, but they did not cover the time span desired for a truly “chronic” experiment. This needed longer-lived animals or humans.

We saw in chapter 8 that the toxicity ratios from the large experiments with beagle dogs turned out to be fully consonant with any values that might have been derived earlier from the experiments with rodents. Nevertheless, the system was never altered. The somewhat confusing and painfully limited n factor continued in use until the new systems for bone based on calculation of dose to the endosteal layer of cells in bone (see chapter 20, also ICRP 1979 and NCRP 1985a)^(b) took over. The beautiful confirmation of the rodent data was recognized but never really pushed the system in the direction indicated in the 1959 ICRP discussion quoted above.

Perhaps one reason for this is the fact that clinical data on humans under chronic exposure conditions had accumulated only for ^{226}Ra , ^{222}Ra and their daughters, and ^{224}Ra . By the original definitions, n would be one for all of these.

(a) Effective energy was then defined as $\sum E F (\text{RBE}) n$ where the E , F , and RBE factors are as defined in note 1. RBE later became Q , the Quality Factor.

(b) This is only one of many major changes introduced by ICRP Report No. 30 and the commentary by NCRP. The approach depicted in figure 16.3 was replaced by the concept of committed dose (see chapter 12). Critical organ was dropped, and the terminology was changed in less major areas. Much of this was alluded to earlier. Since the uses made of research data were not significantly different, we will not repeat the new formulations here. The net effect has been the need for still more research data because of the increase in the number of isotopes considered and the number of parameters for each isotope. The interested reader should consult ICRP 1979 and NCRP 1985a.

FIGURE 16.3. The increase in dose-rate to the critical body organ as a result of continuous use of water contaminated with indicated radioisotopes of different effective half-lives is shown. The concentrations used in making these plots are given to the right of each curve and differ somewhat from the maximum permissible values in the report, where other factors influenced the actual choice of maximum permissible concentrations. (Redrawn from ICRP 1955, p. 33. Reprinted with permission of *The British Journal of Radiology*, London, England, copyright 1955.)

We know it should not be one for ^{224}Ra , since ^{224}Ra behaves more like plutonium than it does ^{226}Ra . Another exception would be thorium, and we have already discussed the problems with it.

There are other complexities beyond our scope here. Suffice it to point out that the NCRP/ICRP maximum permissible body burden for ^{239}Pu using the above computational approach came out to be $0.04 \mu\text{Ci}$ using bone as critical organ, essentially identical to that calculated by the direct method as shown in section III. This was more than a coincidence! We can see how the n factor got its value of five for isotopes other than radium.

The failure of direct utilization of the empirical toxicity data for modern standard setting has been a disappointment to some of the most involved investigators. This was what started the king-sized experiments originally (chapter 8)! However, since the new information indicated nothing was seriously wrong with the figures derived by the computational method, and thoughts were going in other directions, we cannot be unduly distressed that the system was not accommodating. The research data made large contributions to our knowledge of the behavior of bone-seeking radionuclides and their effects despite this possible hiatus. Also, they were used behind the scenes as a control or to "fine-tune" some of the results of dose computations.

D. Special Features of the Basic System and Some Modifications

1. Special Features

It must be emphasized that this basic system had some unique features. In the case of short-lived radionuclides or any that were rapidly eliminated from the body, the limiting dose rate might be reached within a few days or weeks. From that point on, it was assumed that equilibrium existed between intake and loss. The equations used are shown in note 2 at the end of this chapter. In the unlikely case of actual continuous intake as postulated, the critical organ would thus receive the limiting dose rate from that time onward. By contrast, elements with long half-lives and prolonged retention would approach the limiting dose rate very slowly. Indeed, the maximum permissible organ burden associated with the limiting dose rate might be reached only at the end of the assumed lifetime of occupational exposure. These phenomena are illustrated in figure 16.3, taken from an early ICRP report.^(a)

Obviously, this system involves a considerable factor of conservatism for the long-lived, long-retained radionuclides, especially since intakes are most unlikely to be continuously at the MPC.

It should be noted that no cognizance is given in the system to the nature of the biological effect being protected against. The limiting dose rate was determined by groups espousing basic radiation protection criteria. They arrived at their conclusions largely on the basis of work with external radiation sources, except for the bone seekers. They applied their best judgment to the biological data and set exposure levels for the most sensitive functions. For this reason, when the critical organ was whole body, lens of the eye, gonad, or red bone marrow, the allowable dose differed from that for the average tissue.

Genetic effects were included in the consideration, although, as we will see presently, very little information had been gathered at that time on the genetic effects of deposited radionuclides.

As a result of this lack of specification of the effect being protected against, it was the metabolic data on radioisotopes, i.e., distribution, excretion, transfer function, etc., that contributed most. Except for the bone seekers, the accumulating data on effects were not used. Only later did they make a fuller contribution to standard setting.

The chemical form of the isotope was considered, but not nearly to the extent the internal emitter research might have supported. We have seen throughout this book and the cited literature that there are many chemical forms of many radionuclides, and the form sometimes can have a profound influence on biological behavior. However, the committees had to simplify. They simply sorted compounds into two categories, "soluble" and "insoluble," and utilized data for the compounds that best fit the description and were important.^(b) Fortunately, the early researchers had faced this same dilemma and, as we saw with uranium in section III, had also used only the two broad categories, "soluble" and "insoluble." The distinction was applied primarily to inhalation exposures, but not always. Later work developed a more sophisticated system that

(a) At this time, the period of exposure was taken as seventy years, but the principle is the same. This early illustration was chosen to show that this feature of the system was recognized from the beginning.

(b) This applies to the 1959 system and derivatives from it, not to current practices.

utilized more completely the accumulated fund of research data on the influence of chemical form.

All of these special features were fully recognized by the investigators and decision makers as necessary simplifications to allow development of a workable system in a finite time. Some have been eliminated or modified by more advanced systems. Nevertheless, these and other features that will be apparent when we discuss models should be recognized.

2. Modifications

a. Single Exposures

No mechanism was given in the basic system for determining the limits for, or the consequences of, a single intake or a brief series of intakes, except to note that anything less than a continuous intake brought in a factor of conservatism.

Karl Morgan (with Walter Snyder and Mary Ford) took up the question of MPCs of radioisotopes in air and water for short-period exposure at the first Atoms for Peace Conference in Geneva, Switzerland (Morgan, Snyder, and Ford 1956).^(a) The problem at hand can best be stated by quoting from the paper:

Although continuous exposure (MPC) values are necessary for all work with radioactive material, they do not answer many questions relative to the hazards associated with the occasional accident or spill of a radioactive material, and the resultant exposure of short duration—usually referred to as a *single exposure*. . .
(Morgan, Snyder, and Ford 1956)

The same basic types of biological and physical data were needed and employed as for continuous exposure, but the permissible dose was put in three time frames: one week, one year, and seventy years. Also, a detailed appendix was given for derivation of the dose resulting from single exposures to radioisotopes. Any modifications of the biological half-life or other functions attendant upon the single-exposure mode were incorporated into the calculations.

Morgan et al. developed tables showing a function called the "MPI," which was the μCi present initially in the volume of air to be breathed during the succeeding eight hours that resulted in the indicated dose (weekly, yearly, or lifetime limit) for inhalation exposures. It was applied also to injection and puncture wounds. The critical organ after intake might become any one of the tissues important to the basic system. To simplify matters, they chose five situations and developed MPIs and relative hazards for eighty-one radionuclides as follows:

- Case 1—*inhalation of soluble material—critical body organ may be total body, muscle, fat, bone, blood, skin, liver, kidneys, spleen, or thyroid*
- Case 2—*injection of a soluble material by a puncture wound*
- Case 3—*injection of an insoluble material by a puncture wound*
- Case 4—*inhalation of an insoluble material with the lung as critical organ*

(a) It is unclear whether or not this effort received any input from the NCRP/ICRP internal dose committees or was a solo performance by the Oak Ridge group. This author is inclined to believe it was the latter, since the later "official" reports, to be discussed presently, went in another direction.

Case 5—inhale of an insoluble material where some portion of the gastrointestinal tract is the critical body tissue.

The tables are extensive and go through from one to several isotopes of elements up to $Z = 96$ giving either MPI or μCi injected that will result in the allowable weekly (0.3 rem), yearly (15.7 rem), or lifetime dose (150 rem in seventy years). They also give the weight in milligrams corresponding to the smallest value of the above and a calculation of the relative hazard of the radionuclide.

The authors point out that "no official MPI values for single exposures have been agreed upon . . ." and present the figures with the hope they would be useful in "making the final selection of the MPI values for single exposures." Evidently no such action was ever taken. The ICRP reports (see below) on the subject use the same limiting doses as for continuous exposure. They evidently preferred the concept of dose commitment.^(a) Nevertheless, this compendium by Morgan and colleagues was carefully thought out and used the biomedical data effectively. It is surprising that it has not been used more or quoted more, especially since it stood alone for many years.

Over a decade later, the ICRP addressed single intakes in its Publication 10 (ICRP 1968). Here the radiation dose was calculated as a time integral expressed in μCi -days resulting from deposition of 1 μCi . With suitable constants to convert to absorbed radiation dose, the legacy of a single intake could be developed. For occupational exposures, the period for integration was chosen as fifty years. Out of this came the concepts of committed dose, "S" factors, etc., which are taken up in chapter 20.

In both this and the earlier work by Morgan, the application of the metabolic data from experiments where only a single dose was given, which was true of much of the animal work, was probably somewhat more germane than it was to the basic system. We have no evidence of real problems resulting from this dichotomy, but it must be recognized as a flaw in the available research data.^(b)

A few years later, the same committee (Committee-4) of ICRP addressed the kinetics of several intakes in a limited period as well as translocation of radionuclides from an organ of initial deposition (e.g., lung or wound) to other organs (ICRP 1971). This was more a variation of computational methods than the entry of new research data, except for those on translocation and elimination.

These reports contained references to many of the new documents used and went back by use of appendices to the practice of presenting data on individual radionuclides. They also tabulated the metabolic information used.

Finally, these reports introduced the concepts of investigation levels and derived investigation levels.

The members of ICRP Committee-4, a committee that had fairly broad charges, were:

- (a) A review of the entire development given by Morgan in 1971 at an International Atomic Energy Agency (IAEA) symposium indicates that this was indeed the case and gives the reasons (Morgan 1972).
- (b) A very current NCRP report (NCRP 1985a) contains a theoretical mathematical analysis of the long-term differences in tissue content of radionuclides received as single or an annual dose and shows that the difference is small in the long term. This may or may not apply across the board, but it simplifies prospective standard setting.

H. Jammet (Chairman, France)	D. Mechali (France)
D. J. Beninson (Argentina)	C. Polvani (Italy)
G. C. Butler (Canada)	R. Recht (Belgium)
H. T. Daw (U.A.R.)	E. G. Struxness (U.S., Oak Ridge)
H. J. Dunster (U.K.)	F. Western (U.S., AEC)
K. Koren (Norway)	B. Windeger (U.K.)

A task group consisting of Butler (Chairman), Daw, Polvani, and Stewart, plus G. W. Dolphin (U.K.), J. Lafuma (France), W. S. Snyder (U.S., Oak Ridge) and J. Vennart (U.K.) prepared the reports, with help from S. R. Bernard (U.S., Oak Ridge), I. S. Eve (U.K.), M. R. Ford (U.S., Oak Ridge), P. E. Morrow (U.S., Rochester), G. P. Howells (U.K.), and S. D. Simpson (Canada).

b. Population Exposures

The "system" as described was developed for occupational exposures. The problems of radioactive fallout from nuclear weapons tests (chapters 12 and 13), siting of nuclear power plants, and the general arousal of interest in environmental contamination pushed the standard setters into making judgments on allowable population exposures. We saw some of the environmental aspects in chapter 15. The basic story is told well in the various reviews of radiation protection philosophy. The possibility of genetic damage played a large role in the early decisions. However, this was primarily based on work done with external radiation. Only the most rudimentary experiments were done on the genetic effects of internal emitters. They were no help in establishing population exposure levels in the 1960s. The only recourse was calculation of the dose to gonad. Fortunately, few radionuclides concentrate specifically in either ovary or testis. The dose to gonad was frequently larger from radioisotopes deposited in surrounding tissues such as bone than from the deposition in gonadal tissue.

Of the hundreds of radioisotopes listed in the tables, only four (tellurium, tin, zinc, and chromium) turned out to have a portion of the reproductive system^(a) as potentially critical. Only one was close enough to being the critical organ to be placed in bold type.

The limiting levels for external radiation for populations were developed simply by use of a scaling factor, usually one-tenth, from the occupational levels. The same was done for radionuclides, with a few exceptions. Most especially the all-important U.S. Code of Federal Regulations Part 20 and related parts simply gave two tables with the figures for population exposure a factor of thirty lower than those for occupational exposure.^(b)

Our review of the metabolism of radionuclides at environmental levels seen in chapters 13 and 15 gives many reasons to believe that the various metabolic constants derived from higher levels may not always apply to these very low levels. Despite the now large accumulation of information on radionuclides at environmental concentrations, it cannot be said that the basic system has been redone for population exposures with the insertion of metabolic values pertinent to the environmental situation.^(c)

(a) This included the prostate gland.

(b) There were a few specific exceptions based on field findings, e.g., iodine from water-cooled reactors, as we saw in chapter 15.

(c) Morgan and colleagues called attention to the potential for such developments as early as 1959 at the second Atoms for Peace Conference in Geneva, Switzerland (Morgan, Tipton, and Cook 1959).

In recent years, actual experimental work has been done to test for genetic effects of deposited radionuclides. The work has been summarized by the Task Group on Genetic Risk from Internal Emitters of the NCRP Committee on Internal Emitter Standards (NCRP 1985b). It appears that, while there are some special situations, in general, the genetic risk from radiation doses and effects produced by deposited radionuclides are not likely to be greatly different from those from externally applied doses. Thus, the biomedical information on genetic effects does not dictate any urgent need for population standards for radionuclides separate from those derived from experience with external dose effects. On the other hand, the differences in metabolism at environmental levels may dictate special consideration for some radioisotopes. This is a significant gap.

E. Concentrations of Stable Elements

Many of the radioisotopes of interest in the early development of the computational scheme were isotopes of elements normally at very low concentrations in the human body. As the enterprise gained momentum, it was obvious that there was not sufficient information on either the radioactive or stable isotopes of many elements to determine metabolic behavior, select critical organs, etc. Also, knowledge of the concentrations of the stable isotopes of these elements in humans was needed for the development of "Reference Man" (section VI C), determination of pool sizes, etc.

This led to the development at the University of Tennessee in Knoxville and at Oak Ridge of a significant research enterprise to make the necessary determinations, one of the few in-house experimental programs developed specifically around the problems of internal dosimetry.

Dr. Isabel Tipton, an experienced spectrographer and physicist at the University of Tennessee was persuaded to embark on a program with trace metals. It developed into essentially a career with numerous publications appearing year by year with and without collaborators.

The protocol was to use fresh autopsy material from accident victims. Of course, Dr. Tipton never knew how plentiful or how scarce her basic materials might be. However, in view of the tediousness of quantitative spectrographic work, particularly in the earlier days, we can imagine her job was a continuous one. The data were applied directly to the calculations of the Oak Ridge internal dosimetry group.

The information developed in this enterprise contributed also to the growing interest throughout the world in the biology and biochemistry of trace elements in humans and animals. Thus, we find Dr. Tipton appearing on programs with people like Dr. Henry Schroeder, who made at least one career out of the biomedical significance of trace elements.

Since the work of Tipton and her colleagues is scattered over time and in many places, and since her husband, Dr. Samuel Tipton, supplied this author with a nearly complete set of papers, a full bibliography of this important work is given as note 3 at the end of this chapter. This is done to recognize Tipton's role in the internal emitter research effort.

The group at Lawrence Livermore Laboratory (LLL) got together a computer-coded compilation of published information on elemental concentrations in human organs in both normal and diseased states (Anspaugh et al. 1971). This appeared as a UCRL report in three parts. The first part gives the raw data by

atomic number, subordered by organ and suborgan. Also listed are method of analysis, geographical source, age, sex, and number of individuals. In the second part, the data are ordered by atomic number and subordered by organ, suborgan, and general health state. The third part orders the data by organ and suborgan; suborders them by atomic number and general health state. The number of studies, number of individuals, range of high and low means and of individual values, etc., are also given. The second and third parts are more summary in nature than the first.

This very important compilation contains a bibliography of two hundred references in the first volume. It is not easy, however, to ferret out the specific literature reference(s) pertaining to the origin of the data in the second and third parts.

V. Metabolic Data and Metabolic Models^(a)

The importance of the information on the behavior of each radionuclide in the body to the process of standard setting is obvious from the earlier parts of this chapter. Our intent here is to discuss, largely in broad terms, some of the characteristics of the data and the general models that have been developed. This enterprise has drawn extensively on the knowledge gained in conventional pharmacology, physiology, and toxicology, as well as from radioisotope research. However, we will conserve space by concentrating on work concerned primarily with radionuclides.

Each chapter has contained partial reviews of the development of pharmacokinetic data for the nuclides of concern therein. The reader is urged to review these for specifics applicable to this section.

A. Retention Kinetics

Throughout this book, expressions for the retention of radionuclides in organs and tissues have been alluded to. In most instances, two or a series of exponential functions of time described the data reasonably well. For the 1959 NCRP/ICRP reports, the simplifying assumption was made that the loss rate from any tissue could be represented by a *single* exponential function.

Usually, the constant for the longest biological half-life in a multiple exponential series was adopted. Thus, a long biological half-life was utilized, even when a large portion of the material might actually be eliminated by a rapid initial process. This simplification was needed to develop the system. Clearly, it applied a factor of conservatism of varying magnitude to nearly every MPC calculation.

By the time of ICRP Publication 10 and subsequent work, more complete expressions for retention were given. The current system, developed for ICRP Publication 30 (ICRP 1979), gives the complete expressions for retention with full references.

Nevertheless, the system developed in the 1959 NCRP/ICRP reports was used for nearly two decades. The results of utilizing the single exponential scheme thus had many years for impact. Were there problems?

(a) We are using the term "metabolic" in a somewhat colloquial sense, in line with common usage in the radioisotope field and in general toxicology. We mean the behavior of the entity in the body in terms of distribution, excretion, retention, etc. A more eloquent term would be pharmacokinetics.

In chapter 1, the appropriateness of a power function for describing long-term retention of radium (largely ^{226}Ra) in long-lived animals and humans was emphasized. Also, the contrasts between these species and rodents were set out. There was evidence that other long-lived, long-retained bone seekers followed a similar pattern. The 1959 ICRP report devoted a special section to consideration of the power function as one alternative to the single exponential in determining MPCs for bone seekers. Calculations and a table in ICRP 2 give MPC values derived by a power function model for isotopes of strontium, radium, uranium, and plutonium. This was expanded on by Morgan, Tipton, and Cook (1959). The comparison is shown in table 16.1.

TABLE 16.1. Examples of $(\text{MPC})_w$ and $(\text{MPC})_a$ Values Calculated* by the Exponential Law and by the Power Law

Radionuclide	Critical organ	q (μC)	Values Based on Exponential Law		Values Based on Power Law	
			$(\text{MPC})_w$ ($\mu\text{C}/\text{cc}$)	$(\text{MPC})_a$ ($\mu\text{C}/\text{cc}$)	$(\text{MPC})_w$ ($\mu\text{C}/\text{cc}$)	$(\text{MPC})_a$ ($\mu\text{C}/\text{cc}$)
$^{90}\text{Sr} + ^{90}\text{Y}$	Bone	2.1	5.4×10^{-7}	4.4×10^{-11}	8.3×10^{-6}	6.9×10^{-10}
$^{226}\text{Ra} + 30\% \text{ drs.}$	Bone	0.1†	1.2×10^{-7}	9.8×10^{-12}	1.2×10^{-6}	1.0×10^{-10}
^{238}U -natural	Kidney (chem. toxicity)	4.7×10^{-3}	2.9×10^{-4}	1.3×10^{-11}	8.4×10^{-4}	3.7×10^{-11}
^{239}Pu	Bone	0.044	4.5×10^{-5}	5.9×10^{-13}	4.0×10^{-5}	5.3×10^{-13}

* Values in this table are "calculated" values given only for comparison of the exponential and the power law and are not necessarily the final q and MPC values recommended by the ICRP.

† National Bureau of Standards, Handbook H27, Safe Handling of Radioactive Luminous Compound, (1941) Superintendent of Documents, Washington 25, D.C.

Source: Reset from Morgan, Tipton, and Cook 1959. Reprinted with permission of Pergamon Press, Elmsford, New York, copyright 1959. For definitions of q , MPC, etc., see notes 1 and 2.

All values derived by use of the power function are significantly higher than those derived by the exponential method. This was explained, as stated above, by the conservatism of using the longest biological half-life and a rather large value for the fraction of material in the blood that has the long half-life. The MPC values derived from power function retention kinetics were never recommended for use.

This was not a crass disregard of the biomedical data. Let the report state the reasons:

While the MPC values listed in the accompanying table were considered by the Committee in making their final decision, they are not to be considered as recommended values. They are listed to indicate that the Committee has considered carefully this method of estimation and to stimulate research concerning the interpretation and validity of this model. The presentation of the biological data in table 12 on the basis of the exponential model is in large part dictated by the desire to give a unified and economical presentation of the material.
(ICRP 1959, pp. 38-39)

Thus, while the power function fitted the data very well, as we have seen in earlier chapters, the simpler and more conservative choice for protection was the dominant consideration at the time. The current usage of more complete retention functions removes some of this extra conservatism while still being realistic for the long-term situation. (See ICRP Publication 30 and Appendices, ICRP 1979.)

A paper by Morgan, Tipton, and Cook (1959) contains a general summary of many of the biological data used. This Oak Ridge work, given at the second Atoms for Peace Conference, emphasizes many of the biological decisions that entered the picture, in addition to the metabolic data.

With reference to metabolic data, the following points, among others, emerge:

1. The spectrographic analyses for stable elements showed marked geographical variation in some cases. This applied more to elements like cadmium, lead, and chromium than to essential elements such as calcium, iron, zinc, copper, manganese, etc.
2. Other elements showed marked variation with age of the subject e.g., copper and zinc in liver, aluminum in lung, and cadmium in kidney.
3. It was frequently necessary to extrapolate not only from animals to humans, but from the distribution associated with a single intake to that applying to multiple, long-term intakes.

Apropos this last point, it is not easy to find experiments designed specifically to compare the metabolism of isotopes acquired in single compared to multiple doses. In chapter 4, we reviewed work by Stannard and colleagues using rats maintained at a more or less constant body burden of ^{210}Po . There were significant differences in distribution compared to a single dose. The biological half-life was longer, the tissue distribution remained throughout the lifetime closely similar to that at short times after a single injection. There was much less redistribution with time. This is not surprising since it was always no more than one month since the last injection.

We saw in chapter 9 that many of the inhalation exposures continued over many years. This was particularly true of the uranium work at Rochester. Since there was also early data after single exposures, a valid comparison of the two modes could be drawn. However, not much point was made of this comparison in the standard-setting process. Instead, since the bulk of the data resulted from long-continued or at least multiple inhalation exposures, these tissue distribution figures were used more or less as they came out. It is almost impossible to determine which mode prevailed in some cases. Except for inhalation exposures, and of course the exposures of man, the single exposure mode predominated.^(a,b)

(a) Recently, this question has been formally reviewed by the Lovelace group (see chapter 9). Diel and Lundgren (1982) measured whole-body retention and distribution of ^{239}Pu in selected tissues of beagle dogs after a series of two or four inhalation exposures (at half-year intervals) and compared them to those following a single exposure. The experiments indicated that each exposure behaved essentially independently of the others. The authors cite one human case with repeated inhalation exposures to plutonium-uranium fuels. The same picture was evident (Ramsden, Bains, and Fraser 1978). By contrast, repeated inhalation exposures to $^{144}\text{CeO}_2$ in mice and ^{137}Cs particles in dogs indicated greater retention in the lungs (Boecker, Thomas, and McClellan 1977; Lundgren et al. 1980). The authors speculate that longer-range radiation from ^{144}Ce produced progressive lung damage, which interfered with clearance processes.

(b) The analysis in NCRP 1985a mentioned earlier also addresses this point.

The internal emitter dosimetry people at Oak Ridge, with help from Marquette University, devised an experiment specifically to test the practice of using single exposure data for calculating MPCs in water for continuous exposure (Cook, Morgan, and Barkow 1956). They chose ^{60}Co and found very little difference in its distribution between single and multiple doses. This result seems to have led to the conclusion in the internal dose committees that the practice was not fraught with serious difficulties.

At the time of the development of "the system," there were few alternatives. However, there is now much information that could contribute to a valid comparison of single and multiple dose kinetics. This information has never, so far as is evident, been assimilated overtly into modified calculations by the recommending bodies. It is doubtful if anyone has been harmed by this omission, but it seems to have been ignored; at least it is seldom mentioned in the standard-setting process in the later years. It was incorporated into EISs and appears to have been considered in the development of the data for specific isotopes in the reports of the late 1970s. The significance, if any, of this hiatus is not addressed to the extent that it should have been.

On the other hand, the recent publications (especially ICRP 30 with its voluminous appendices) give ample and specific information that should allow detailed tracing of the data used in each case and provide a basis for modifications if such are needed. Indeed, the volume of material is so large that it seems doubtful if another such effort would be needed for at least a decade. Only the honing of estimates of risk (see later section) appears to be essential.

B. Metabolic Models

The simple assumptions described above might be regarded as technically metabolic models since a single generalization was applied to a large number of radionuclides, tissues, and organs. However, there were different figures for each situation. Still more generalized schemes were developed. It is these that we will consider in this section and in section VI.

1. Biokinetic Model

The assumptions applied in the 1959 NCRP/ICRP reports for metabolic behavior of the elements were replaced in 1979 (ICRP Publication 30) by a systemic biokinetic model utilizing several compartments. It was applied, with a few exceptions, in all of the dose calculations. The basic model is shown as figure 16.4.

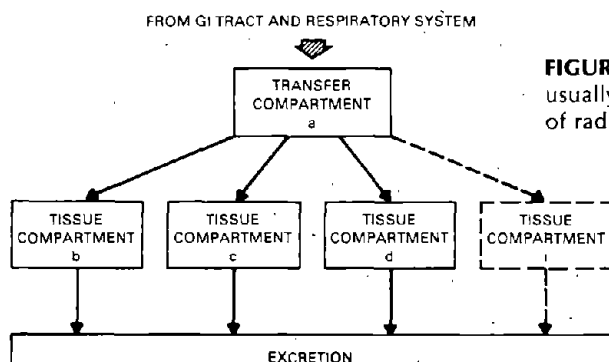

FIGURE 16.4. Mathematical model usually used to describe the kinetics of radionuclides in the body; exceptions to this model are noted in the metabolic data for individual elements. (Redrawn from ICRP 1979. Reprinted with permission of Pergamon Press, Elmsford, New York, copyright 1979.)

It is immediately apparent that this is more like the compartmental models used generally in physiology and pharmacology. The first compartment, (a), is intended to cover the time taken for translocation from the site of entry into body fluids for transfer to the various tissues. This is assumed to have first-order kinetics to time (i.e., a single exponential) with a half-life of 0.25 days unless otherwise stated. Each organ or tissue is assumed to have one or more compartments into which the radionuclide settled and was subsequently translocated elsewhere or to the excretion pathway. The release rate takes into account both the clearance rate into the compartment from the transfer compartment and the respective losses of the *stable* isotopes of the element from the compartments b, c, d, etc. A factor for radioactive decay of the radionuclide is then added.

This model is obviously more complex than the one utilized by NCRP/ICRP in 1959. Yet, it hews to the line of using exponential kinetics (by way of decay constants). It has been criticized by some because there are no terms for feedback, i.e., movement in the direction opposite to the arrows, a normal physiological process. Those who developed the model were aware of this and caution that estimates of dose along the route of excretion should not be attempted from this model. The final result is probably not significantly influenced by the omission of feedback. The constants used are, fortunately, derived from the biological data. The rates measured are already *net* rates, *including feedback*. Details of the equations used can be seen in ICRP Publication 30, Part I, p. 18 (ICRP 1979).

The origin of this model cannot be pinpointed to any single group of workers, even to any single country. It simply appeared as a result of the ICRP Committee II's efforts. Since it is much like the families of compartmental models used throughout physiology and pharmacology, there is probably little need to establish its origin or attempt to give credit.

2. Bone Model

A very large effort has gone into dosimetric models for bone. These are described in ICRP Publication 30 and, with more historical perspective, in the NCRP report cited earlier (NCRP 1985a). They are also considered briefly in chapter 20. Space does not permit detailed discussion. We should remark, however, that no single tissue has received as much research attention, or had so many schemata developed around it, as has bone. That should be obvious from the earlier chapters.

The only complete generalized and self-contained *metabolic* model (as compared to *dosimetric* model) is the one developed for the behavior of the alkaline earth elements in bone. This was the result of much hard work by a special task group of ICRP Committee II chaired by John H. Marshall of ANL. It was adopted by the Commission in May 1972 (the task group was organized in 1968), and it has come to be known as "The Marshall Model." It was published as ICRP Publication 20 and also, after peer review, in the journal *Health Physics* (ICRP 1973).

A very abbreviated summary of this model is given as note 4 at the end of this chapter.

The report contains much more than a model. It is a fine summary of much of the biokinetic data for important bone-seeking radionuclides in the body. Despite its ninety-two pages, a plea is made at the end for more data. These include bone surface data and soft tissue data for the heavier alkaline earths,

the relative activity in new and old bone, more data on ^{90}Sr in human bone, and information on rates of resorption in the radium cases.

The other members of the task group were J. Liniecki, E. L. Lloyd, G. Marotti, C. W. Mays, J. Rundo, H. A. Sessions, and W. S. Snyder. Acknowledgments were made to R. E. Rowland, R. C. Thompson, J. Vennart, and P. Groer, the last for review of the mathematics.

It is a commentary on the difficulty of the task that no comparable generic model has yet been developed for the all-important actinide elements in bone. Nor have generalized models been developed for other tissues, except for lung and gastrointestinal tract, as we will see in the next section. There have been numerous models for specific elements. An early one was developed for hexavalent uranium by Struxness and colleagues at Oak Ridge (Struxness et al. 1956). A revised and updated model is being developed by Wrenn, Roswell, and Durbin (1982).^(a) Many animal models have been made for plutonium; environmental models for iodine, etc.; but these are not as close to the standard-setting process as those we have been discussing.

It seems possible that a generic model for actinides in bone may be "just around the corner." At the 1979 meeting on actinides in man and animals, an entire section was devoted to metabolic mobility of actinides. The Battelle group presented a comparison of plutonium metabolism and pulmonary tumors in dogs and rats (Mahaffey et al. 1981). Skrable and his colleagues at the University of Lowell (Massachusetts) described retention functions in general (not just for actinides) and summarized current models for the actinides applicable to radiation protection (Skrable, Chabot, and Johnson 1981).^(b) A comparison is made of the ICRP Publication-2 model, the ICRP Publication-30 model, a mammillary model, and one involving blood-organ transfer kinetics. Bernard, a long-experienced modeler for the Oak Ridge group, presented what has been termed an "Urn" model for plutonium. The term comes from the concept of a container (i.e., an urn) holding different colored balls and representing an organ of the body containing different atoms (Bernard 1981). In the final paper of the session, Cuddihy (Lovelace Foundation) addressed actinide modeling in both bone and liver with the conclusion that newer laboratory data do not support current ICRP models (Cuddihy 1981). However, this is not surprising since the ICRP model was developed to assure protection of workers, and this was conservative in a number of aspects.

These models are hardly simple. Also, it may be that the new work will tear apart the model already in place for alkaline earths rather than add one for actinides. Only the future can tell. Nature guards her secrets zealously!

VI. Other Models

A. Lung Model

One of the most urgent needs in the early development of standards for radionuclide uptake was one for the behavior of particles and gases in the respiratory tract. As discussed in earlier chapters, many assumptions appeared in the

(a) It was published in 1985 (Wrenn et al. 1985), and expanded upon by Durbin (1986).

(b) Kenneth Skrable has risen rapidly to be currently one of the most active and prolific developers of the mathematical aspects of internal dosimetry.

MED days in connection with the behavior of particles and gases in the respiratory tract. These were usually part of a consideration of a specific situation and specific radionuclides. We also saw, particularly in chapter 9, the broad extent to which the influence of particle size was researched, both during and after the war years.

At the Tri-Partite Conferences on Permissible Doses, various individuals gave information on behavior in the respiratory tract of the radionuclides they had been working with. Gradually some generalizations emerged. By the time of the third Tri-Partite Conference, held at Arden House, Harriman, New York, a scheme was proposed and adopted that became the first general lung model.

This early model is shown in table 16.2A. While the scheme is said to have been put forward by Morgan and Eisenbud^(a) (Taylor 1984), it is clear that there was input from Brues, Bugher, Cipriani, Hamilton, Marinelli, and Mitchell. Also, it is hard to believe that Wright Langham was not furthering the enterprise in view of his long-standing interest in inhalation problems.

TABLE 16.2A. Early Lung Model

	Soluble Compounds	Insoluble Compounds
Exhaled	25%	25%
Deposited in upper respiratory passages	50%	50%
Deposited in lungs	25% (This is taken up into the body)	25% (Of this, 15% is eliminated in 24 hours, 10% remaining in the lungs indefinitely)

Source: Reset from minutes of Third Tri-Partite Conference, Taylor 1984, Appendix 23.

A very similar model appeared in the 1959 ICRP report. It is reproduced as table 16.2B. It will be noted that the principal difference is in the retention behavior of insoluble compounds in the lower respiratory passages. Later still, the retention half-times for thorium and plutonium were increased to three hundred days.

It will be noted that neither model says anything about particle size or its influence. They were simply assumed to apply to the average respirable aerosol. Likewise, chemical form was marked only as "soluble" or "insoluble." There was more discussion at the Tri-Partite Conferences of the differences between nose and mouth breathers than the differences due to particle size! This was indeed painting with a broad brush, but it met the needs of the time for devising standards.

It was recognized that these models were too crude for permanent use, indeed that much more information could be applied relatively soon.

(a) This was when Merrill Eisenbud was at the New York Operations office of the AEC. He was deeply involved with industrial hygiene aspects of all AEC operations, particularly those involving uranium.

TABLE 16.2B. ICRP Publication 2 Lung Model*Particulates in respiratory tract of the standard man*

Retention of particulate matter in the lungs depends on many factors, such as the size, the shape and density of the particles, the chemical form and whether or not the person is a mouth breather; however, when specific data are lacking it is assumed the distribution is as shown below.

Distribution	Readily Soluble Compounds (%)	Other Compounds (%)
Exhaled	25	25
Deposited in upper respiratory passages and subsequently swallowed	50	50
Deposited in the lungs (lower respiratory passages)	25 (This is taken up into the body)	25*

*Of this, half is eliminated from the lungs and swallowed in the first 24 hours, making a total of 62½ per cent swallowed. The remaining 12½ per cent is retained in the lungs with a half-life of 120 days, it being assumed that this portion is taken up into body fluids.

Source: Reset from ICRP 1959, p. 153. Reprinted with permission of Pergamon Press, Elmsford, New York, copyright 1959.

Consequently, in 1964, the ICRP appointed a special task group under Committee II, the Task Group on Lung Dynamics (TGLD), to devise a more sophisticated model. Respiratory tract parameters, transport functions, and the effect of particle size were all studied in depth. The group was chaired by Paul E. Morrow, University of Rochester, an outstanding respiratory physiologist-pharmacologist. Other members were: David V. Bates, Royal Victoria Hospital, Montreal; Birney Fish, Oak Ridge National Laboratory; Thomas T. Mercer, University of Rochester; and Theodore F. Hatch, University of Pittsburgh. Consultants and special contributors were Drs. Donald A. Morken (University of Rochester); G. Parry Howells (U.K., Belmont, Surrey); J. Rundo (U.K., AERE Harwell); Dr. Halloway (Oak Ridge); and Messrs. W. Downs, L. Leach, A. Raabe and Mrs. Léon Greenwold, all at the University of Rochester at the time.

As mentioned in chapter 9, the new model was a quantum jump from the 1959 version. The first report appeared as a journal publication in 1966 (TGLD 1966), record time for such a complex venture. Deposition is addressed as a function of particle size in three major divisions of the adult human respiratory tract—naso-pharyngeal (N-P), tracheobronchial (T-B), and pulmonary (P). The lymph nodes and lymph are considered as a depository separate from the respiratory system. Clearance constants are provided for three major classes of compounds divided according to duration of retention in the lung (see below) for each of the major components, as well as constants for translocation to body fluids and lymph nodes.

The model was an instant success. It began to be used immediately, albeit informally, in calculations of the day. It was especially useful for the numerous EISs being developed at the time. It was quoted, with slightly modified

clearance constants, in ICRP Publication 19, which concerned plutonium (ICRP 1972). However, since this was a blue covered book, by ICRP convention the model's inclusion there was not an official adoption or recommendation. This had to await the publication of the official document on *Limits for Intakes of Radionuclides by Workers*, i.e., Publication 30, in 1979.

The "official" model as described in ICRP Publication 30 has the usual updating of certain constants but incorporates the fundamental plan worked out by the task group. Deposition was shown as a function of particle size (activity median aerodynamic diameter [AMAD]) for the three regions of the respiratory tract. It applied to aerosols of AMAD between 0.2 and 10 μm .

The clearance functions were drawn from a compartmental model using deposition values for an aerosol of 1 μm AMAD. The basic features of these schemes are shown in figure 16.5A and B. The text of the ICRP report gives all of the equations necessary for each step as a series of first-order, interlinked, differential equations.^(a)

FIGURE 16.5A. Deposition of dust in the respiratory system. The percentage of activity or mass of an aerosol which is deposited in the N-P, T-B, and P regions is given in relation to the Activity Median Aerodynamic Diameter (AMAD) of the aerosol distribution. The model is intended for use with aerosol distributions with AMAD between 0.2 and 10 μm and with geometric standard deviations of less than 4.5. Provisional estimates of deposition further extending the size range are given by the dashed lines: For an unusual distribution with an AMAD of greater than 20 μm , complete deposition in N-P can be assumed. The model does not apply to aerosols with AMADs of less than 0.1 μm . (Redrawn from ICRP 1979. Reprinted with permission of Pergamon Press, Elmsford, New York, copyright 1979.)

The only major differences between the 1966 and 1972 versions and the one in ICRP Publication 30 are as follows: (1) the dose to the N-P region was considered so small that it could be neglected; (2) the T-B, P, and L regions were combined into a single target tissue with a mass of 1,000 g. The latter was done because of the problems of deciding which region to use for dose calculation and uncertainties concerning the location of the cells at most risk.

The former is not acceptable to many investigators. The nasopharynx is a demonstrated site of origin of cancer from inhaled substances. Many do not

(a) For the convenience of the reader not having access to ICRP documents, they are reproduced in the 1985 NCRP report cited earlier (NCRP 1985a).

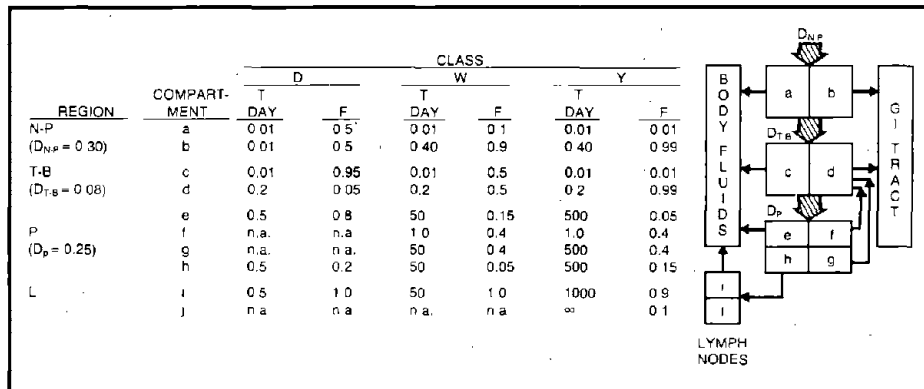

FIGURE 16.5B. Mathematical model used to describe clearance from the respiratory system. The values for the removal half-times, T_{a-j} and compartmental fractions, F_{a-j} are given in the tabular portion of the figure for each of the three classes of retained materials. The values given for D_{N-P} , D_{T-B} , and D_P (left column) are the regional depositions for an aerosol with an AMAD of 1μ . The schematic drawing identifies the various clearance pathways from compartments a-i in the four respiratory regions, N-P, T-B, P and L. n.a. = not applicable. (Redrawn from ICRP 1979. Reprinted with permission of Pergamon Press, Elmsford, New York, copyright 1979.)

consider the dose to this region as always negligible. Work with chemical toxicants confirms this view. Furthermore, the lumping of the major compartments is not universally considered as better than the 1966 version.

Also, the particle size range in the original model was 0.01 to $100 \mu\text{m}$ AMAD. The reduced range in the official model (0.1 to $10 \mu\text{m}$) probably reflects the difficulties of obtaining good data below $0.1 \mu\text{m}$ AMAD and the unimportance of particles above $10 \mu\text{m}$.

It is important to realize that the clearance model is not tied irretrievably to a particle size of $1 \mu\text{m}$ AMAD as given in the legend to figure 16.5B. The H_{50} (committed dose equivalent for fifty years) can be adjusted from the calculated values given in the supplements to ICRP Publication 30 by using the following relationship:

$$\frac{H_{50}(\text{AMAD})}{H_{50}(1 \mu\text{m})} = f_{N-P} \frac{D_{N-P}(\text{AMAD})}{D_{N-P}(1 \mu\text{m})} + f_{T-B} \frac{D_{T-B}(\text{AMAD})}{D_{T-B}(1 \mu\text{m})} + f_P \frac{D_P(\text{AMAD})}{D_P(1 \mu\text{m})}$$

where D_{N-P} , D_{T-B} , and D_P are the deposition probabilities in the respiratory regions for a given AMAD shown in figure 16.5A and f_{N-P} , etc., refers to the fraction of committed dose equivalent resulting from deposition in the named compartment.

Not shown in the official version of the model is the detailed tabulation of biological half-lives determined in many species for many chemical forms of a large number of elements, along with recommended values for many elements under single or multiple exposure regimes given in the 1966 publication. Also, the pulmonary clearance classifications were given in detail there for various inorganic compounds: carbides, sulfides, sulfates, carbonates, phosphates, oxides and hydroxides, halides, and nitrates with enumeration of those elements

whose compounds fell into each of the three major clearance classifications, i.e., Class D, minimal retention (days); Class W, moderate retention, intermediate clearance (weeks); and Class Y, avid retention, slow clearance (years). The serious student of lung models needs to study this information from the 1966 report to understand the classifications used in the new ICRP report and model.

This model is applicable not only to aerosols of radioactive materials, but to any aerosol. With small modifications, it could, and *should* be used in routine industrial hygiene practice. It is an invaluable contribution to the entire field.

We can expect modifications in detail as forecast in the recent NCRP report (NCRP 1985a), and from new task groups of the NCRP and ICRP. New research in this field is going on particularly at the Lovelace Foundation and at Battelle (see chapter 9).

B. Gastrointestinal-Tract Models

Next to respiratory-tract parameters, some of the most important figures in the development of standards concern the gastrointestinal tract. Before doses could be calculated, and before it could be ascertained whether or not a section of the gastrointestinal tract might be considered as a critical organ, decisions needed to be made regarding its characteristics. The question of what mass to use for the gastrointestinal tract and the mass of the contents was discussed briefly at the Tri-Partite Conferences. The data for "standard man" (see next section) gave figures for a "present ICRP value" of 2,000 and 2,300 g, respectively (Arden House meeting). However, this was not in the detail needed. Suggestions for rate of passage as well as weights of the contents of different portions of the gastrointestinal tract came from the United Kingdom. Sir Edward Pochin sent a proposed model for these to Karl Morgan by letter in October 1953. In the interim between 1954 and 1959, the members of NCRP/ICRP Committees II drew together the information and came up with a fairly detailed description of the gastrointestinal tract, which appears in the 1959 ICRP report, as shown in table 16.3 below.

TABLE 16.3. Gastrointestinal Tract of the Standard Man

Portion of GI Tract that is the Critical Tissue	Mass of Contents (g)	Time Food Remains, τ (day)	Fraction from Lung to GI Tract, f_a	
			(sol.)	(insol.)
Stomach (S)	250	1/24	0.50	0.625
Small intestine (SI)	1100	4/24	0.50	0.625
Upper large intestine (ULI)	135	8/24	0.50	0.625
Lower large intestine (LLI)	150	18/24	0.50	0.625

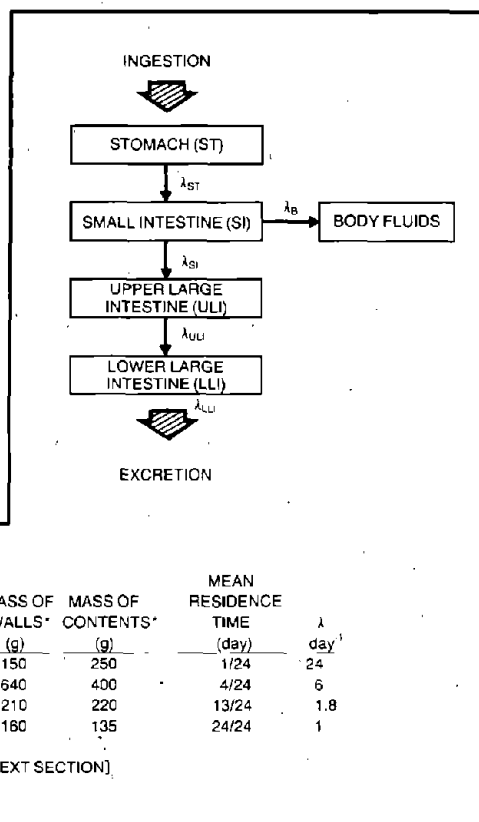

Source: Reset from ICRP 1959. Reprinted with permission of Pergamon Press, Elmsford, New York, copyright 1959.

In the interim between the "old" ICRP/NCRP report (i.e., 1959) and the "new" ICRP report (1979), two important contributions came from the United Kingdom. Eve (1966) reviewed the physiology of the gastrointestinal tract in relation to doses from radioisotopes, and Dolphin and Eve (1966) summarized the relevant dosimetry.

For the new ICRP internal emitter report (ICRP 1979), a compartmental representation was added, along with slightly different figures for mass and residence times. Also, the complete dosimetric model, with equations for each step, was developed in the text. This includes activity transferred to the gastrointestinal tract from the respiratory system, as well as outward transfer to body fluids and excretion.

The model and constants are shown in figure 16.6.

FIGURE 16.6. ICRP model for kinetics of radionuclides in gastrointestinal tract. (Redrawn from ICRP 1979. Reprinted with permission of Pergamon Press, Elmsford, New York, copyright 1979.)

Not shown in the model is the fact that a factor between zero and one is applied in the calculations depending upon the penetration characteristics of the radiation from each radionuclide. Many radiations penetrate the mucus layer of the gastrointestinal tract only with difficulty, as well as being absorbed to a considerable extent in the gut contents. In the absence of specific information to the contrary, the factor is taken as unity for photons and beta particles, 0.01 for alpha particles and fission fragments, and as zero for recoil atoms. Without this factor, doses to the gut wall for radiations of low penetrability would be grossly overestimated.

The cited NCRP report (1985a) points out that the proliferating cells in intestinal crypts, which are probably the most important potential target cells, are not at the interface between intestinal wall and intestinal contents. They are approximately 1,000 μm within the intestinal wall. For low-energy radiations and those with low penetrability, the assumption that the critical cells are at the interface lends considerable conservatism to the model. A second important feature of the behavior of radionuclides in the gastrointestinal tract is their absorption rate. This figures in all of the calculations for MPC in water. It also figures in all of the annual limits on intake by the oral route using the NCRP/ICRP

system. The factor, f_w in the 1959 system, f_1 in the 1979 system, is idiosyncratic for each element. It probably varies also with the chemical form ingested.^(a)

Most of the values used in the 1959 reports were based on gut absorption in animals given the radionuclide in the fasting state by the process of gavage. We have discussed the pitfalls of this methodology in earlier chapters. However, there was not much else to use at the time of the earlier calculations.

With the advances of internal emitter research, values for humans became more regularly available. The data came from measurements of the absorption of the radionuclides in fallout by dietary intake (chapters 12 and 13) and experiments on volunteers (chapters 13 and 20). These were applied as feasible.

A center for research activity on gastrointestinal absorption of various radionuclides has existed at Battelle, Pacific Northwest Laboratories. M. F. Sullivan has essentially spent a career on the subject with a series of collaborators.^(b) Typical information generated can be seen in a review directed at the actinide elements prepared as an "in-house" document and later published (Sullivan 1978, 1980, 1981). This contribution delved further into the influence of chemical form and indicated that "soluble" and "insoluble" compounds of the actinides were *both* poorly absorbed from the gastrointestinal tract. The work also demonstrated little difference among the species for americium and plutonium, much greater variation in the rat for the other elements used, but not in dog or guinea pig.

Nearly every laboratory doing metabolism of internal emitters made its contributions to the figures for gastrointestinal absorption, as seen in earlier chapters. Special mention should be made of the ongoing studies at ANL (Larsen et al. 1981). This group examined the solution chemistry of plutonium and other actinides with reference to gastrointestinal tract absorption. A marked influence of valence state was described.

An important perturbation, alluded to earlier, appeared in some of this work. For some elements at least, the fractional absorption appeared to increase as the absolute concentration decreased. Thus, at the low concentrations associated with environmental and population exposure, fractional absorption could be considerably greater than at the higher levels used in the gavage experiments. This was especially noted for uranium in work of Durbin at the University of California, Berkeley, and later by Wrenn at Utah and New York University. In fact, the relationship was regular enough to be graphed in a discussion of the subject at the Snowbird actinide symposium in 1979 (Wrenn 1981). The work presented is part of a current joint effort by Durbin and Wrenn.^(c)

It will be noted in figure 16.7A that much of the relationship depends on a single point (average) at the lowest concentration ingested. Because of the importance of such relationships to setting standards for drinking water, the EPA asked that it be reviewed at a National Workshop on Radioactivity in

(a) This complication is sidestepped in part by reasoning that chemical forms that are different on entrance merge to a more common form by reactions in the gut. Thus, only "soluble" and "insoluble" are distinguished.

(b) Much work from the old Hanford Laboratories bears on this subject also, as mentioned in chapters 6, 7, and 8. The names of J. Ballou, V. H. Smith, and R. C. Thompson should be looked for.

(c) The relationship was described first by Durbin in an unpublished manuscript mailed to members of NCRP Scientific Committee-34 (Durbin 1976). It has become less obvious with further work, as described.

Drinking Water convened in May 1983. The results were published as a special issue of *Health Physics* (Vol. 48, No. 5, 1985). In it, Wrenn and six collaborators, including Durbin, reviewed most of the extant data on metabolism of ingested uranium and radium (Wrenn et al. 1985). This included a redo of the relationship between uranium uptake from the gastrointestinal tract and the intake in $\mu\text{gU/kg/day}$. The result is the graph shown as figure 16.7B. There is still a suggestion of the relationship shown in figure 16.7A, but the slope is less steep, and the data from rats indicate hardly any effect at all.

FIGURE 16.7A. (Left) Effect of concentration on gastrointestinal-tract absorption of uranium. (Redrawn from Wrenn 1981. Reprinted with permission of RD Press, University of Utah, Salt Lake City, Utah, copyright 1981.)

FIGURE 16.7B. (Below) A later plot of gastrointestinal absorption of uranium plotted as a function of intake. Details of the symbols can be found in the original reference. They pertain to the origin of the figures. Experiments in which the concentration of U ingested was more than $10^3 \mu\text{gU/kg/day}$ were omitted in fitting the curves, since they appear unlikely to be encountered in environmental exposures, which was the primary thrust of this work. (Graph redrawn from Wrenn et al. 1985. Reprinted with permission of Pergamon Press, Elmsford, New York, copyright 1985.)

It was thought for a while that this phenomenon might be a general one. However, examination of data for other radionuclides, e.g., plutonium, indicated more or less invariant absorption at different intake concentrations (Harrison et al. 1981). It may well be that differences among radionuclides, if they do occur,

could reside in differences in specific activities, but dietary factors appear to be of importance also (chapter 15).

Some new, higher gastrointestinal absorption figures found their way into the f_1 values used in ICRP Publication 30 and Supplements. They can have a large effect on exposure standards.

There is also the problem of the large range of values for gut uptake. Harrison (1981) at the NRPB in the United Kingdom has addressed this subject for inorganic actinide compounds. The ICRP (1979) value and the range of experimental results are shown in table 16.4, taken from the Harrison paper.

TABLE 16.4. Gut Uptake Values Recommended by ICRP for Occupational Exposure to Inorganic Actinide Compounds Compared to Experimental Results

Actinide	ICRP Value % Absorption	Experimental Results	
		% Absorption	Species
Thorium	0.02	0.005—1	Rat, guinea-pig, human
Protactinium	0.1	0.006—0.2	Rat, hamster
Uranium*	5	0.06 —5	Rat, hamster, dog, human
Neptunium	1	0.05 —1.5	Rat, hamster
Plutonium*	0.01	0.001—0.1	Mouse, rat, hamster, guinea-pig, rabbit, pig, dog
Americium	0.05	0.006—0.1	Rat, hamster, guinea-pig, rabbit
Curium	0.05	0.003—0.1	Rat

*Both U and Pu are assigned values for more soluble and less soluble forms; the values given are for the more soluble forms.

All results given are for inorganic compounds of the elements in normally fed adult animals.

Source: Reset from Harrison 1981. Reprinted with permission of the National Radiation Protection Board, Oxon, England, copyright 1981.

Some of this range may be due to differences in concentration in the gut, and thus to the phenomenon described for uranium above, but how much cannot be determined from the data. Only a systematic investigation of many important elements at many intake concentrations can sort out how much of "biological variability" is due to one cause over another.

In addition, there are the usual effects of age and diet on gastrointestinal uptake of various elements. A recent summary for the actinides can be found in the paper by Harrison (1981).

It might seem that figures for gastrointestinal uptake would be among the easiest to come by. Recent experience shows that this is not true and that the use of single values is a very great simplification. Furthermore, the choice of figures sometimes makes a very large difference in the applicable standards. Already some of the uptake figures chosen for ICRP Publication 30 have had to be re-examined. There is a spate of new work that must continue to completion if we are not either to spend millions of dollars with unnecessarily low guidelines or apply a mistakenly high guideline and thereby produce biological damage. We need to get much more serious about the role of chemical form for each major radionuclide and for each class of radionuclides.

C. Reference Man (Standard Man)

The development of Reference Man began too at the Tri-Partite Conferences. At the first conference in Chalk River, Ontario, it was considered essential to formulate a set of biological parameters for both internal and external radiation exposures. Naturally, some parameters had already come into common usage, but it was agreed that without a carefully specified set of values the biological basis for published standards would have to be presented each time. If they differed, the standards might differ in an uncontrolled manner. Each health physicist would have to begin "ab initio"^(a) in every instance. Also, any adjustment of values to meet the needs of special situations would not have a known base line from which to work.

External radiation standards needed only fairly simple specifications of organ mass, dimensions, and elemental composition. For the calculation of permissible levels for radionuclides, much more was needed, including the mass of many more organs, more details of the chemical composition of organs and tissues, patterns of intake and excretion, water balance, respiratory parameters, etc., some of which have already been described.

This collection of information became known as "Standard Man." Minutes from the Chalk River Conference contain the first specifications. Herman Lisco, a pathologist at the University of Chicago and ANL, and Mary Jane Cook, Oak Ridge National Laboratory, whom we met in chapters 7 and 8, supplied data for the mass of organs. Chemical composition of the total body and various tissues was taken from a standard textbook of physiological chemistry of the day (Hawk, Oser, and Somerson 1947).^(b)

There were modifications at the later Tri-Partite Conference at Harriman House and at the Sixth and Seventh International Congresses of Radiology. An agreed-upon set of characteristics for "Standard Man" appeared in the 1954 and 1959 reports of the Internal Dose Committees of NCRP/ICRP. This was the work of the committees, and no special group was designated as responsible in the reports.

We will make no attempt to give details here. It should be emphasized, however, that the figures are not averages or medians of any specified population group. Judgment was used in the selection to try to present values that would be most likely to represent a typical individual of the European or American population. Since these are heterogeneous populations, the figures do not reflect ethnic or regional populations. Nevertheless, on balance, "Standard Man" could be regarded as weighing 70 kg, being 170 cm high, between twenty and thirty years old, a Caucasian of Western European habit or custom and living in a climate with an average temperature of 10° to 20°C.^(c) "He" was used for calculation of the MPC and other values in the 1954 and 1959 NCRP/ICRP reports.

The extent to which judgment, rather than purely statistical factors, entered into the decision is apparent from the minutes of the Tri-Partite Conferences. Somewhat amusing are statements agreeing that the weight of a given organ is

(a) Term used by ICRP in the report to be cited.

(b) This was, of course, before the large-scale investigations by Tipton referred to in section IV.

(c) Much colder or warmer climates would have considerable influence on water intake and diet.

so many grams. The committees were, of course, fully aware of the wide range of values which might occur. But they did not confuse things by putting ranges on their chosen values. They simply devised a standard man and advised anyone with knowledge that his situation differed markedly from the standard to use his own values. Since the calculations were used mostly for prospective evaluations and the setting of general standards, there were few takers of this proffered flexibility.

This work was greatly expanded by the appointment of a special task group of ICRP. The circumstances and charge can be seen by a quotation from the book-length report produced by this task group:

In December of 1963, Committee II of ICRP requested that the Commission establish a Task Group for the revision and extension of the standard man concept. At the suggestion of the Commission, the name was changed later from "Standard" Man to "Reference" Man. The charge to the Task Group on Revision of Reference Man was in the following terms:

Estimates of dose equivalent resulting from human exposure to radionuclides that may enter the body depend upon many characteristics which must be indicated clearly if the Commission's recommendations on dose commitment, body burden, and MPCs are to be applied correctly. For this reason the Commission's recommendations relating to dose equivalent from internally deposited emitters have been specified in terms of a "Reference Man" whose characteristics, so far as relevant to the Commission's recommendations, are carefully specified. Because of the increased emphasis on exposure of the population, it is desirable that the specifications of the previous Standard Man be reviewed and revised to take account of present needs for evaluation of exposure to radiation.

The task group should review those characteristics of man that relate directly or indirectly to intake, metabolism, distribution in the body, and retention of the various isotopes of concern. In particular, it is desired to define Reference Man, in the first instance, as a typical occupational individual, and it is important that some indication of variability of the occupational group about this norm be indicated. In addition, differences due to age, sex, or habits should be indicated where possible with particular emphasis on fetuses, infants, and children.

It is expected that a separate task group will consider the problem of devising a lung model, and thus the Task Group on Reference Man need not consider the mechanism of inhalation, deposition, or lung retention. It is expected also that some independent assistance on the gastrointestinal tract will be available but that this will be offered to the task group directly.

It is clear that the work involves two aspects: (1) the revision and extension of a Reference Man which represents a typical radiation worker, and (2) extension of the concept to give an indication of the extent of individual variation among grossly normal individuals and to include dependence on age, sex, and to some extent other factors whose effects must be considered in estimating dose to individuals of the population. (ICRP 1975)

The members of the task group were:

W. S. Snyder, U.S., Oak Ridge, Chairman
 M. J. Cook, U.S., Oak Ridge
 L. R. Karhausen,
 E. S. Nasset, U.S., Rochester and later in retirement, Berkeley, CA
 G. Parry Howells, U.K., Belmont, Surrey
 I. H. Tipton, U.S., University of Tennessee and Oak Ridge.

Primary responsibilities were divided as follows: (1) anatomical values for Reference Man, a very large section which included many physiological and

biochemical parameters along with conventional anatomical values (L. Karhausen);^(a) (2) elemental composition of tissues and the whole body (I. H. Tipton); (3) intake and excretion (G. Parry Howells); (4) literature referencing, cross-checking, editing and indexing (M. J. Cook); and (5) physical data on dosimetry and final editing (W. S. Snyder). E. S. Nasset contributed first as a consultant and then as a member of the task group. Nasset was an expert in nutrition and gastrointestinal physiology and probably contributed especially to these aspects, as well as to the overall product.

The final publication is a closely knit volume of 480 pages, with over 130 tables, not counting summary and addendum. Despite this, the task group emphasizes that *only* characteristics significant for estimating radiation doses are included. There was no attempt to embody "all known characteristics of man." For this, the reader would need to turn to the multivolume comprehensive *Handbook of Physiology* published by the American Physiological Society over a period of years (APS Handbook).

The ICRP Reference Man report has a summary of model values for fifty-one elements and an appendix showing Specific Absorbed Fractions of Photon Energies for Reference Man (see chapter 20). It met its purposes admirably and supplies continuously most of the basic data needed for the computational approach to standard setting. Nevertheless, as recognized by the ICRP and others, applications to population standards require more information on infants and children and more information on non-Caucasian groups. These are being produced gradually. The Japanese have already published a version of reference man more applicable to their anatomical and dietary characteristics (Tanaka, Kawamura, and Nakahara 1979; Tanaka, Kawamura, and Nomura 1981). However, these developments are beyond the scope of this history, except to mention them as a portent for the future.

The ICRP has recently announced appointment of a new task group, chaired by C. R. Richmond (Oak Ridge), to update and expand the model for Reference Man.

VII. Validation in Humans

In a sense, every experiment constitutes a validation or invalidation of previous work and/or of the hypotheses behind it. Here we are interested in research, primarily data from humans, that bears so directly on the processes or the input figures of standard setting that they could reflect on the validity of the standards themselves. The earlier phases bore primarily on validation of the metabolic models and the metabolic factors used. This still continues. Beginning early, but not bearing fruit until much later, are studies bearing on the presence or absence and the nature of biological effects.

In the United States, this work has been concentrated in only a few institutions (ANL, Hanford Environmental Health Foundation, and PNL [Hanford], Los Alamos, University of California, Berkeley). It is more convenient to structure the discourse around elements and general operating experience than around institutions, as we have done in some previous chapters.

(a) This section included total body; integumentary system; skeleton, cartilage, bone marrow, teeth, etc.; hematopoietic system; lymphatic system, spleen and thymus; skeletal muscle system; cardiovascular system; digestive system; respiratory system; urogenital system; endocrine system; central nervous system; special sense organs; and the characteristics of the components of pregnancy.

Since the standards for radium isotopes and for radon and its daughters were derived primarily from studies involving humans rather than indirectly, a formal validation process of the type to be presented in this section need not be described. The consistent failure to find bone sarcomas at levels below the maximum allowable, even with large increases in the size of the study groups for radium, was considered validation enough. Fortunately, the conservatism of the radium standard (see page 1413) was sufficient to encompass the incidence in later years and at lower radiation doses of carcinomas. Difficulties with the WL concept (see page 1416) make conclusions about the validity of the radon and radon daughter standards less than rock solid. Yet, even the most recent NAS-NRC analysis (NAS-NRC 1988), after a review of the epidemiologic data, comes up with estimates of lifetime risk of lung cancer mortality due to lifetime exposure to radon progeny within the range of earlier estimates.

A. Plutonium and the Transplutonic Elements

The largest validation enterprise by far concerns the isotopes of plutonium and to a lesser extent other transuranium elements for reasons that are now obvious.

1. The Eighteen Patients

The work with eighteen hospitalized patients done during World War II under the auspices of the MED was described in chapter 7 (see also Langham et al. 1950, 1980). The work was entirely directed toward metabolism of plutonium. This group remains one of the most important, since the administered dose is known accurately. The patients were at Strong Memorial Hospital, Rochester, New York, the University Hospital in San Francisco, the Billings Hospital in Chicago, and the Oak Ridge Hospital. The data, with addition of some long-term excretion figures from Los Alamos workers, were the basis for the equations used for over three decades to calculate body burdens and organ burdens of plutonium.^(a)

The first serious attempts at reevaluation of these data came from Patricia Durbin at the University of California, Berkeley. It started with a UCRL report (Durbin 1971) entitled, "Plutonium in Man: A Twenty-Five Year Review." One refinement was separation of data from patients with diseases that might modify circulation, iron metabolism,^(b) gastrointestinal and kidney function, etc., from those that could be viewed as normal in these functions. It was apparent that there were differences among the patients consistent with an influence of their medical problems. Therefore, a second refinement was added—individual analysis of the data from each patient. In addition, the original data were reviewed in the light of advances in analytical techniques and possible errors introduced by the old methods. Durbin added new data using occupationally exposed persons and animal experiments for comparison.

It became clear that "the original data were good and that the original analysis was sound. The new data from occupationally exposed persons and from animal experiments, and the use of the iron analogue, contributed more to understanding the old results than did the difference in analytical approaches. The initial tissue distributions, excretory patterns, and predictions of long-term

(a) See Langham equation, and Langham-Healy equation in chapter 7.

(b) By this time, the transport of plutonium in combination with transferrin, the iron complexing moiety, and the similarities of plutonium and iron had been established.

plutonium elimination presented here do not differ in substance from the original analysis . . . only in detail" (from Durbin 1971, pp. 94-95).

A major contribution of Durbin's analysis, besides the important validation of earlier work and models, was the construction of a more generalized metabolic model for plutonium in humans. This model included excretion equations that were the sums of exponentials rather than the power functions used in the Langham and Langham and Healy models.

Since the original report on these patients still remained classified (see chapter 7), Durbin rendered an additional service by giving pertinent information on each patient, without revealing identity.

The UCRL report was followed by a published review by Durbin. It was given at the 1972 conference of the Utah Project (see chapter 8) and was entitled, "Plutonium in Man: A New Look at the Old Data" (Durbin 1972). The review is replete with graphed metabolic functions showing data from sheep, dogs, and exposed workers, and where the points from the patients fit.

The conclusions differ slightly from those quoted from the 1971 report. There is careful analysis of the forms of plutonium in the blood and their correlation with urinary excretion. Anemia and gastrointestinal problems reduced plutonium excretion by one-half in urine and feces respectively, but half-times were not changed. The exponential notation predicted somewhat greater excretion than the power functions. The model developed predicted equal amounts of plutonium in bone and liver fifteen years after exposure, assuming adequate dietary intake of iron.

A comparison involving both species and mode of representation is shown in table 16.5A, and a comparison of long-term plutonium excretion predicted from sums of exponentials versus power functions is shown in table 16.5B.

The authors explain that it took three different power functions to describe the data depending upon the time interval. However, for our purposes, the original Langham model (see chapter 7) for daily urinary (Y_U) and fecal (Y_f) excretion rates will be quoted. This is:

$$\begin{aligned} Y_U &= 0.2t^{-0.74} && \text{in per cent per day} \\ Y_f &= 0.63t^{-1.09} && \text{in per cent per day} \end{aligned}$$

where t is in days and is >1 .

Durbin (1972) developed the multicomponent exponential equation as follows:

$$Y_U = \sum_{i=1}^5 a_i \exp(-0.693t/(t_{1/2})_i),$$

where the values of the intercepts, a_i , are 0.41, 0.12, 0.013, 0.003, and 0.0021% dose/day, and the values of the biological half-lives, $(t_{1/2})_i$, are 1.2, 5.5, 42, 300, and 4,000 days, for components 1 to 5 respectively, and

$$Y_f = \sum_{i=1}^5 b_i \exp(-0.693t/(t_{1/2})_i),$$

where the values of the intercepts, b_i , are 0.60, 0.16, 0.012, 0.002 and 0.0012% dose/day, and the values of the biological half-lives, $(t_{1/2})_i$, are 2.0, 6.6, 56, 380, and 4,000 days, for components 1 to 5, respectively.

This is now known in the literature as "The Durbin Equation." It is obvious from table 16.5A that there can be almost as much variation introduced by different models applied to a given species as there is among species. Also, the

sums of exponentials (table 16.5B) predict more excretion by a small but significant amount than the power function. Durbin does not commit herself to favoring one over the other model as "validated" by the reworking of the data. She does emphasize that the rework indicates progressively more plutonium (relatively) in liver over a fifty-year working lifetime. On balance, the conclusions are that some fine-tuning is needed but nothing drastic.

In 1971, Dr. Durbin spent considerable time at Rochester combing the original patient records.^(a) Presumably, she did the same thing at the other institutions. This not only fed data into her reviews, but sowed the seed for possible remeasurement of excreta and in-vivo counting of the survivors. The program of following up radium workers and patients had been very successful (see chapter 1). Could not the AEC (or ERDA) put such a task in place for plutonium, e.g., in the Center for Human Radiobiology at ANL or the Transuranium Registry, discussed later?

The possible political consequences of such a move troubled the AEC headquarters staff (see chapter 7). An ad hoc committee was convened in May 1974 (DBER 1974) to recommend on the scientific merit of studying not only the few individuals still alive, but of mounting an exhumation program similar to that current for radium patients. The committee consisted of Eugene P. Cronkite, Marvin Goldman, Roy Talmage, and Betsy Stover (chairperson). They concluded that the importance of nailing down the figures from these eighteen patients warranted such a program, provided all or nearly all could be done. A program did get started at the Center for Human Radiobiology, but it was kept at a low profile. Two or three exhumations have occurred, and the cremation ashes of one patient were made available for measurement (Rundo 1983). No data have been published yet so far as this author knows. Permission for exhumation was denied in several instances.

As a result of Dr. Durbin's efforts and the interest of all concerned, it was possible in 1973 to hospitalize three of the patients for formal study of plutonium excretion and in-vivo plutonium measurements. Two were placed on the metabolic ward at Strong Memorial Hospital in Rochester and measured by John Rundo from Argonne in collaboration with local staff. The third was hospitalized at the Argonne facility. The results are given in an important paper by Rundo (1981) at the Snowbird Actinide Workshop.

The case that received the plutonium intramuscularly was not followed through because the size of the initial dose was in question. The original dose was given in a leg, which was amputated four days later because of preexisting cancer. (See Case Cal-3 in Durbin 1972).

Two of the HP cases (see table 7.1) were studied completely. Details are given in table 16.6A, taken from the Rundo (1981) paper.

It turned out that the excretion of plutonium at these long times after injection (10,000 days) was very significantly higher than predicted by either the Langham or Durbin models. The retention model for plutonium developed by

(a) It was this author's privilege to help make the arrangements for this, including interviews with the physician attending the patients still alive and in the Rochester area. There were high hopes that some of the original tissue blocks, especially for bone, could be obtained and sections made for analysis of plutonium by modern methods. Unfortunately, the Pathology Archives had discarded those tissue blocks a few months before!

ICRP in Publication 19 (ICRP 1972)(a) was in good agreement at the later times, but not at earlier times. The data are shown in table 16.6B. In one subject, the rate of excretion began to increase at about 6,000 days, reached a maximum at 9,500 days, and declined from that point on (Rundo 1981).

TABLE 16.6B. Daily Excretion at 10⁴ Days as Percentages of Injected Dose

	Urine	Feces	Total
Subject 40-009	2.52×10^{-3}	1.05×10^{-3}	3.58×10^{-3}

This increase in excretion at long times was not totally unexpected. Some of the workers of long standing from the MED group showed tendencies for overestimation of the body burden when the Langham equation was used (Rundo 1981). As seen in table 16.5B, the daily excretions of plutonium by these two subjects at 104 days was at least an order of magnitude higher than predicted by

(a) Details of this equation are given by Rundo (1981) and are in ICRP 30 (1979).

the models in current use. Does this invalidate the models? It does not. The models were developed from data to a maximum of five years. The re-examination of the data in no way seriously invalidated either model for times less than five years. Also, the ICRP model, which works well at very long times, "grossly underestimates the excretion rate at early times, overestimates it by a factor of more than 2 at around 1,500 days, and yet is approximately correct at 104 days" (Rundo 1981, p. 258).

The only caution is not to rely on the original models without changes of constants for very long times. Rundo points out the Langham equation provides a good description of the urinary excretion rate up to fifteen hundred days for both of the HP subjects and that Durbin's equation is about equally good after ten days. He gives graphs for each case and for a long-term Los Alamos worker.

It should be noted that the change away from the kinetics of the model means that plutonium body burden at later times would be *overestimated* if the older models were used. Thus, any errors that might have been introduced by use of the equations for long periods of retention would have been on the side of safety. Note, too, that the urinary excretion rates at these times are so small that even a factor of ten is not very much plutonium.

We will hope that additional information on tissue content will be made available from this all-important group of patients. This would put the capstone on this facet of the validation process. Permission for exhumation was denied in several instances.

The Center for Human Radiobiology did contribute later via a joint paper by Bob Rowland, director of the center, and Patricia Durbin (Rowland and Durbin 1976). This involved computation of the probable radiation doses to liver and bone of all eighteen patients and correlation with the effects noted in the radium cases at comparable doses. They concluded that the dose to liver was probably not high enough (in terms of the then-extant ideas about the radio-sensitivity of liver) to be carcinogenic. Comparison of the bone-surface doses for plutonium, with radium doses that had induced bone tumors, indicated that six of the cases had received doses high enough to be regarded as carcinogenic. Neither bone nor liver tumors had yet appeared in any of the cases (nor have they to date [1987]). Thus, to a small degree, this operation, intended to check out metabolism, allowed a small foray into validation of the effects portion of the standard.

2. The Twenty-Five Los Alamos MED Workers

Let us give the setting by quoting the introduction from the first major report on the subject produced at Los Alamos:

This is the story of how 25 young men were heavily exposed to plutonium at what is now the Los Alamos Scientific Laboratory (at Los Alamos, New Mexico) in the days of the Manhattan Project during World War II and of what has happened to them in the subsequent 27 years. All but a few of the subjects of this study were college science majors who were drafted into the Army and assigned to a Special Engineering Detachment of the Manhattan Project. All were sent to Los Alamos (Project Y) in 1944 or 1945 and given various technical jobs in the Chemistry and Metallurgy Research Division. In these capacities, they were engaged in processing plutonium prior to fabrication and testing of the first atomic bomb. Almost all of these subjects had body burdens of plutonium estimated from the urine assay for

plutonium used at Los Alamos before 1950 that ranged from 0.1 to 1.2 μg (0.006 to 0.08 μCi). (Hempelmann, Richmond, and Voelz 1973)^(a)

Recall that the maximum permissible body burden of plutonium was 0.04 μCi . Therefore, some of this population were definitely "over the line." They were selected for the study since they represented a population of great interest to validation of the standard.

This enterprise is a living memory to Wright H. Langham who was "Mr. Plutonium" in biomedical circles throughout the world. Again, we can catch the flavor best by quoting from the first report:

This report of the health of war-time Los Alamos plutonium workers was inspired by Wright H. Langham and is dedicated to his memory. Wright's keen interest in plutonium is known to everyone and, as one of the if not the world's authority on plutonium biochemistry and toxicity, he was the first to be called upon by our government as well as those of other countries whenever plutonium problems arose. His ultimate concern, of course, was the toxicity of plutonium in man and, in this connection, he organized the UPPU Club composed of the subjects of this study. He kept in close touch with the Club members by periodic circulation of friendly UPPU Newsletters. It was undoubtedly the humor and enthusiasm expressed in these Newsletters that has been responsible for the excellent cooperation of the UPPU Club members in this study.

Wright's intense interest in plutonium continued until his untimely death. In fact, an early draft of this manuscript and a number of now declassified war-time reports on plutonium experiences were with him at the time of the fatal plane crash. Although Wright died before he could write his interpretation of the present data, he contributed enormously to the report in the course of discussions of the subject during the winter of 1971-1972. Although we are well aware that the study suffers greatly by not having Wright's direct participation, the authors have tried to write a report of which he would have been proud. In an effort to make the report into a personal living story, which it was to Wright, we have included many of the anecdotes that Wright loved to tell.

(Hempelmann, Richmond, and Voelz 1973, Preface)

Since the whole thing began around body burdens estimated from urinary excretion, the acronym for the club, "UPPU," becomes obvious.^(b)

This study was not primarily to validate the metabolic model. However, since the measurements were made, comparisons to older computations are given. It was to validate the safety of the standard in terms of effects that the work was undertaken. The first full report covered twenty-seven years. Its abstract is reproduced as follows:

(a) Hempelmann, the senior author on this first report, was for many years professor of experimental radiology at the University of Rochester School of Medicine and Dentistry. (We saw some of his earlier work in chapter 1.) However, he was the physician in charge at Los Alamos during the war years and has close ties to these workers and their health. He consistently revisited Los Alamos to keep up with the work. He and his colleagues also published a paper in the *Proceedings of the Third IRPA Congress* on the biomedical follow-up of these workers, a more abbreviated version of the Los Alamos report (Hempelmann et al. 1974). In his present status as professor emeritus, he still maintains contact with this important study.

(b) It was this author's privilege to visit Los Alamos when the club was back for a five-year check-up. No winning sports team or college reunion gathering could have had more spirit.

Twenty-five male subjects who worked with plutonium during World War II under extraordinarily crude working conditions have been followed medically for a period of 27 years. Within the past year, 21 of these men have been examined at the Los Alamos Scientific Laboratory, and 3 more will be studied in 1973. In addition to physical examinations and laboratory studies (complete blood count, blood chemistry profile, and urinalysis), roentgenograms were taken of the chest, pelvis, knee, and teeth. The chromosomes of lymphocytes cultured from the peripheral blood and cells exfoliated from the pulmonary tract were also studied. Urine specimens assayed for plutonium gave a calculated current body burden (excluding the lungs) ranging from 0.005 to 0.42 μCi , and low-energy radiation emitted by internally deposited transuranic elements in the chest disclosed lung burdens probably of less than approximately 0.01 μCi . To date, none of the medical findings in the group can be attributed definitely to internally deposited plutonium. The bronchial cells of several of the subjects showed moderate to marked metaplastic change, but the significance of these changes is not clear. Diseases and physical changes characteristic of a male population entering its sixth decade were observed. Because of the small body burdens on the order of the maximum permissible level in these men so heavily exposed to plutonium compounds, we conclude that the body has protective mechanisms which are effective in discriminating against these materials following some types of occupational exposures. This is presumably explained by the insolubility of many of its compounds. Plutonium is more toxic than radium if deposited in certain body tissues, especially bone; however, from the practical point of view, plutonium seems to be less hazardous to handle. (Hempelmann, Richmond, and Voelz 1973, abstract)

The report contains pictures of the original wooden "D" building, which housed the chemists and metallurgists (see figure 8.13B). Quite obvious are the hood exhausts from the first floor venting without filtration at roof level or below. It is related that the air intake from the hoods went through an electrostatic precipitator, but it is obvious that the chances are high of receiving someone else's exhaust without entry via the hood intake. It seems likely that the bulk of these exposures were by inhalation, although ingestion may have occurred also.

By 1972, a computer code called PUQFUA^(a) had taken over the calculations. The analytical methods were greatly improved, along with the updating of the computational model. The report cites 1953, 1957, and 1962 estimates of body burden and compares them with the 1972 estimate. Almost all of the 1972 figures were higher. The average for the twenty-five subjects was 1.6 times the earlier Langham estimate. Some were higher by as much as a factor of five or six. Only two of the estimates were lower in 1972 than earlier. As a result, eighteen of the twenty-five workers now checked out above the maximum permissible amount at some time, whereas only twelve were in that category in the earlier documents (cited in the report).

The associated radiation doses (calculated) for twelve clear inhalation cases were lowest in bone (5 to 17 rad in about twenty-four years), higher in liver (28 to 95 rad in the same time), and highest in lung (63 to 200 rad). Diligent physical examination and tests showed only the possible changes in lung alluded to in the abstract.

In-vivo measurements of plutonium were possible by this time. The investigators measured plutonium in the chest cavity and searched out areas of lymph nodes, ribs, and some miscellaneous tissues.

(a) Plutonium Body Burden (i.e. $q=Q$) From Urine Analysis.

The search for chromosome damage in blood cells was expected to yield positive results. Experience with the uranium miners and animal studies pointed in that direction. However, the chromosome analysis "indicated minimal radiation damage to the lymphocyte series even at a high level of exposure of the patient" (Hempelmann, Richmond, and Voelz 1973, p. 18).

Sputum cytology work similar to that applied to the uranium miners to detect incipient or actual lung cancer was inconclusive. There were problems with the role of tobacco smoking and the collection of standardized sputum samples.

The report ends without drawing firm conclusions. More time was said to be needed. Obviously, the apparent lack of overt biological effects could be regarded as validating the standard. The higher body burdens calculated from urine analysis are not compared to the in-vivo counting, presumably because there were no earlier in-vivo counts. The phenomenon seems to have been relegated by the authors to the changes in calculation code and perhaps better analytical chemistry.

A five-year update of these workers was contained in a report by the Los Alamos people in 1978. Since this involved other populations and there was nothing new to report in the twenty-six workers,^(a) we will postpone consideration of it until later.

The next full-dress report, this time published in *Health Physics*, was issued in 1979 (Voelz et al. 1979a). By this time, two of the individuals had died, one of a myocardial infarction, the other accidentally. The other twenty-four were examined and measured; twenty-two of them by return to Los Alamos.

The PUQFUA program was adjusted in the interval on the basis of the results of autopsy samples (see next section) and also to better accommodate statistical fluctuations in the samples. The 1977 figures (published in 1978) were lower on the average than the 1972 values and more like the earlier ones. The average calculated body burden was about 60% of the 1972 value.

In the occupational histories, which were given, it is noted that some of the subjects worked with other radionuclides in addition to plutonium. Any such exposures appear to have been low enough to remove fear that insults from additional radioactivity complicated the findings.

The medical histories, given in detail in the published paper, were again devoid of evidence of radiogenic cancers or other dyscrasias possibly associated with plutonium exposure. Only two cancers of any kind were found, and these, cancers of the skin, were attributed to other causes by the Los Alamos group.

The mortality experience in the group was about one-half that expected in white males in the United States. This may reflect the relatively high socioeconomic status of the workers or only the fact that the group is too small to generate reliable mortality statistics.

The latest five-year re-examination had been completed but not yet published at the time this chapter was completed. George Voelz gave much of the information as part of the Health Physics Society's Mid-Year Topical Symposium on Radiation Epidemiology in January 1983.^(b) This report involved a total of 224 persons (Voelz et al. 1983). Informally it appears that the health status of the group is consistent with or better than their age group in general.

(a) In both this and the 1978 report, the occupational MED group is given as twenty-six rather than twenty-five. The identity of the added person is probably hidden somewhere in the in-house reports.

(b) Voelz gave both a formal paper and a "refresher course" of several hours' duration.

The net result of this enormous task is validation of the plutonium standard in terms of effects, except for problems of the small size of the group.

Hail to the Spirit of the UPPU Club!

3. Other Los Alamos Workers

It was obvious that the small group of MED workers could not supply the extensive information on late health effects needed for a proper epidemiologic study. In 1974, the Los Alamos group expanded the study to include all Los Alamos workers, current and past, with body burdens of plutonium of 10 nCi (0.01 μ Ci) or more. The review concentrated on mortality statistics and cancer incidence in the workers. For a control group, the cancer mortality rates between 1950 and 1969, and between 1969 and 1974, among Los Alamos County male residents who lived or worked moderately close to the facility was used.

The first major report was given at an IAEA symposium on late effects of ionizing radiation (Voelz et al. 1978), which was quickly followed by a report at a conference for radiation accident preparedness held in Oak Ridge (Voelz et al. 1979b). The results can be reviewed best by a quotation from the 1978 paper:

A borderline excess of deaths due to the combined cancers of lymphatic and haematopoietic tissues did appear in Los Alamos male residents between 1950 and 1969. Neither mortality rates in females from 1950 to 1969 nor incidence rates in males from 1969 to 1974 were high. This suggests that any excess, if real, was probably occupationally induced prior to employment at Los Alamos or during early years when controls of all hazards, including chemicals, in the work place were not up to current standards. Tumours of lymphatic and haematopoietic tissue differ in aetiology, and it is not suggested that any one factor could be expected to be responsible. Before and during Los Alamos employment some workers could be expected to have been exposed to various hazards of modern technology, including radiation in all its forms and organic and inorganic chemicals.

High incidence rates of cancers of the digestive tract in white males were noted from 1969 to 1974, although mortality from these cancers was significantly low between 1950 and 1969. Digestive cancer mortality rates in females were significantly high from 1950 and 1969, and the incidence rates in females remained above average from 1969 to 1974. No simple explanation is possible, but occupational exposures seem a less likely explanation than socio-economic and cultural factors, counteracted at first by an exaggerated healthy worker effect. Males were selected for active military service originally, and since 1945 for active employment in a demanding industry and for regional geographic mobility. Females were subject to selection in most cases only by marriage to such males. Both sexes could share the same white-ethnic, social or behavioural risk factors, counteracted in the males during the first years by the strong healthy worker, healthy migrant, and/or healthy military effects.

It should be noted that neither mortality nor incidence data suggest an excess of cancer of the lung in the male population of Los Alamos County.
(Voelz et al. 1978, Discussion section)

This expanded study of Los Alamos workers and population did not invalidate the standards. However, even this larger group was considered too small for conclusive results until further information is gathered. A still wider ranging study was desired. This will be discussed presently.

4. Other Worker Populations

As stated at the outset, efforts at validation involved two quite different phenomena—the metabolic parameters and the metabolic models and the

health status of individuals exposed to plutonium. The former involved development of formal autopsy programs and will be discussed as part of the Transuranium Registry. The latter is an ambitious effort to follow up all plutonium workers at Hanford, Los Alamos, Mound Laboratory (Miamisburg, Ohio), Oak Ridge, and Savannah River. With unexposed controls, this population could number about twenty thousand, but only a small number will have measurable body burdens of transuranic elements.

It should be noted that studies of *population* exposures around nuclear energy installations such as Rocky Flats were discussed in chapter 11. In a sense, these can be regarded as potential validation procedures for population exposure standards. However, since they were not designed for this purpose, and the results are still too qualitative to serve for validation, we will let the discussion in chapter 11 suffice.

5. Autopsy Programs for Plutonium and the Transuranics

a. Independent Programs

As early as 1949, a small program of tissue sampling was started at Hanford. The object was radiochemical analysis for ^{239}Pu , for comparison with amounts calculated from excretion measurements. Bone, liver, and lung were routinely analyzed, and, in 1960, collection of pulmonary lymph nodes was added since most of the exposures were judged to be by inhalation.^(a)

This work was reported in depth by Newton et al. (1968) at a Hanford symposium. The conclusions were, unequivocally, that the predominant source of plutonium contamination was not from occupational sources, but from fallout from nuclear weapons testing. The measured and predicted tissue contents squared very nicely using the predictions of the fallout model. Thus, the work validated the fallout model insofar as any model can be relied upon.

It is interesting to note that one of the highest concentrations (130×10^{-3} d/m/g; not really very much) occurred in the lymph nodes of a worker with ten years of work exposure.^(b) This is reminiscent of the autopsy findings on one of the workers involved in the Los Alamos criticality accident (Mr. Kelly). He had had considerable work exposure to plutonium. The animal work (chapter 9) was showing very high concentrations in the lymph nodes. So did his.

Another point of interest was the fact that liver depositions were greater than lung in many instances. Unfortunately, the data for bone were inconclusive.

During the autopsy program at Los Alamos, concentrations in gonad (especially testis) were found to be higher than expected. Indeed, with the high relative biological effectiveness of alpha emitters, the calculated doses in rem over long periods elicited concern. It turned out that some of the early results on very small samples were in error. Harry Schulte, the group leader of Industrial Hygiene at Los Alamos, sent a memorandum to recipients of the early version of the report (Schulte 1973) stating that the data on larger samples of gonadal

(a) A program aimed more at fallout levels of contamination was reported by Krey, Bogen, and French (1962). They were impressed by the high percentages of the maximum permissible population dose delivered to lungs, pulmonary lymph nodes, and gonads by the fallout plutonium found in autopsy tissues. This program does not seem to have been extended.

(b) The late start on measuring lymph nodes resulted in many blank spaces under that heading.

tissues were practically all below the minimum detectable level. Nevertheless, concern for genetic effects of plutonium persisted until experimental work, quoted earlier, indicated no special sensitivity toward deposited radionuclides for mutations in the mouse, at least.

b. The U.S. Transuranium Registry

At a Hanford Biology symposium in 1967, H. D. Bruner from AEC Headquarters (whose work we met in chapters 8 and 9) presented a paper entitled "A Plutonium Registry" (Bruner 1968). He pointed out that full information for long-term evaluation of internal contamination requires full input from not only the attending occupational physician, but also from health physicists, industrial hygienists, and chemical engineers. In his view it is expecting too much of the busy industrial medical person to collect and collate all of the necessary information. Furthermore, it is unrealistic to expect the individual physician to write the final clinical reports for such cases. The follow-up period is much too long. In Bruner's view, only a formal organization could respond adequately to the needs. He suggested such an organization for the plutonium cases that then numbered about 330 persons. He also suggested including other transuranic elements fairly soon.

Evidently the same idea had been incubating in the mind of W. D. ("Dag") Norwood, the industrial physician at Hanford. Events moved rapidly with official blessing from AEC Headquarters (i.e., funding), and Dag Norwood became the Registry's founding director. A contract was let with HEHF in Richland, Washington, for a National Plutonium Registry. In 1970, the name was changed to U.S. Transuranium Registry (USTR).

The purposes and *modus operandi* can be gained from the Program Description in a recent annual report of the USTR:

The purposes of the USTR are to study the patterns of distribution, concentration and retention of transuranics in exposed individuals by radiochemical analysis of selected post-mortem tissues; to evaluate the estimates of body or lung burdens made during the life of the individual and compare them with estimates based on the analysis of selected tissues obtained after death; to assess toxic histopathologic changes, if any; to compare findings in animal experiments with estimates in humans who have transuranic depositions; and to serve as a national and international resource center concerning the transuranic elements in man.

An exposed individual is one who has a documented exposure to one or more transuranics, either with or without a measurable deposition. The study population has been composed primarily of occupationally exposed employees of the various Department of Energy (DOE) contractors and Nuclear Regulatory Commission (NRC) licensees. This does not exclude, however, individuals exposed to these elements in research institutions or the uniformed services. The last two resources have not yet been approached on a large-scale basis.

The Registry, working through major DOE contractors and several NRC licensees, identifies employees who have the potential for internal deposition of transuranic elements. These employees are interviewed by contractor medical personnel to verify the potential for internal deposition of transuranic elements. These employees are interviewed by contractor medical personnel to verify the potential exposure and to seek voluntary participation in the Registry at the time of the interview. A medical and health physics release is obtained from those employees who volunteer to participate. Previously terminated employees also have been identified and contacted for participation if they have evidence of a transuranic

deposition. This contact may have been made either by the Registry or by the participating contractor, depending upon prior arrangements.
(HEHF 1983, p. 1)

There have been 647 valid autopsy releases from Hanford, Rocky Flats, Los Alamos, and Mound Laboratory; none to date from Oak Ridge or LLL. A few employees of licensees and three volunteers swelled the total to 825. Of these, 220 have been autopsied, and radiochemical analyses have been completed on 147 cases. This is a major effort at validation.

A few notes on procedure are in order:

At the time of death a post-mortem examination is performed and a complete written pathology report is obtained along with supporting medical information and health physics data. A set of histopathological microscopic slides is obtained for later review. The radiochemical analysis of donor tissues is performed at either the Los Alamos National Laboratory (LANL) or the Rocky Flats site (Rockwell International Company, Golden, Colorado). The laboratories maintain an ongoing quality assurance program involving the comparison of analytical data to ensure comparability and uniformity in the analyses. A library of previously analyzed tissue sample aliquots has been kept so that reanalysis of specimens or analysis for other radioisotopes may be performed.

The Registry has identified special prosecutors to assist with the post-mortem examination and thereby assure uniform selection and preparation of tissues for analysis. These prosecutors are available at major contractor sites.
(HEHF 1983, p. 2)

The autopsy results to date have shown that estimates made by in-vivo counting and excretion measurements tended to be higher than those based on tissue analysis. However, this was considered largely due to analyzing "nonrepresentative" portions of the organ samples obtained. The Registry has been making a strong effort to obtain donations of the whole body rather than the usual small autopsy samples. The amount in total skeleton is especially important to measure because of the known variations in deposition of plutonium and other transuranics in different bones. Permission has now been obtained for twenty-four whole-body examinations upon death, and there have been seven deaths in the group. The first contained so little transuranic radionuclide that total tissue analysis was given up. The other was a case of deposition of ^{241}Am .

Validation of the metabolic model for this man is not discussed very directly in the reports. If the estimate of the in-vivo measurements, $0.3 \mu\text{Ci } ^{241}\text{Am}$ systemic burden with initial depositions of 0.5 to $1.1 \mu\text{Ci}$, is compared to the summed tissue samples, $0.15 \mu\text{Ci}$ with initial deposition of about $0.6 \mu\text{Ci}$, it appears that the conclusions drawn from small tissue samples are being confirmed. The in-vivo estimates seem to be high by a factor of about two. Yet, we find in the 1981-1982 annual report the statement, "Preliminary data from the first whole body tissue analysis indicate that the health physics estimate of systemic burden is comparable to the post-mortem estimate in this case" (HEHF 1983, p. 2). This is the same case; the difference is in point of view. Details appear to need considerable adjustment, and the computer codes are being modified accordingly.

When the hundreds of analyses involved are considered, it could be concluded that losses in the radiochemical procedures could sum up to a factor of two. Also, the computer codes are far from infallible. We must await developments.

The factor of two appeared again very recently in a presentation by McInroy (one of the radiochemical analysts involved in tissue analyses at the DOE Human

Tissue Laboratory at Los Alamos) and colleagues from Los Alamos (McInroy et al. 1982). They report on tissues from 180 autopsy cases from various facilities. The plutonium levels were, in general, those associated with fallout. For the twenty cases with the highest depositions (maximum 0.05 μCi), the urinalysis data gave estimates "that are high by factors of 2-3, or more." The authors note the considerable variability in whole-body distributions and suggest that each exposure incident is unique and must be evaluated on the basis of chemical form, solubility, particle size, mode of entry, and duration of exposure. Incidentally, some of the cases were in the Transuranium Registry.^(a) The others were from the Los Alamos series, which began well before the USTR was organized. It must be emphasized that the USTR is not an epidemiologic study. It does not engage in measuring mortality rates for any specific diseases; this is left for others. The analyses do, however, include careful and complete histopathologic examinations.

The personnel serving the Transuranium Registry and management are listed below:

United States Transuranium Registry Management

Bryce D. Breitenstein, Jr., M.D., President,
 Hanford Environmental Health Foundation (HEHF)
 Scott E. Dietert, M.D., Manager, Research, HEHF
 Margery J. Swint, M.D., Director
 Ronald L. Kathren, Consultant, Battelle, Pacific Northwest Laboratories
 (now full-time with HEHF)
 Patricia Blackburn, C.P.S., Secretary

Prosectors

Robert W. Bistline, Ph.D., Rocky Flats Plant
 Gerald Dagle, D.V.M., Ph.D., Battelle, Pacific Northwest Laboratories
 James McInroy, Ph.D., Los Alamos National Laboratory
 E. J. Reagan, M.D., Mound Laboratory
 William H. Carlton, Savannah River Plant

Advisory Committee

J. W. Poston, Ph.D., Chairman, College Station, Texas
 R. D. Evans, Ph.D., Vice Chairman, Scottsdale, Arizona (resigned 1986)
 P. W. Durbin, Ph.D., Chairman, Technical Advisory Committee, Berkeley, California
 C. W. Mays, Ph.D., Salt Lake City, Utah
 J. Newell Stannard, Ph.D., San Diego, California
 Langan W. Swent, San Francisco, California
 George Voltz, Los Alamos

The Advisory Committee serves also for the Uranium Registry, which will be discussed presently. For many years, Bryce D. Breitenstein, Jr., M.D., was director, and Kenneth R. Heid was associate director of the Transuranium Registry (HEHF 1983). There have been a few changes since (HEHF 1985).

6. Mancuso Study

An ambitious epidemiologic study of selected radiation workers was initiated in 1964 by the AEC and continued by its successor agencies. It was spearheaded until 1977 by Dr. Thomas Mancuso at the University of Pittsburgh. Mortality

(a) Note added in proof: Further details can be seen in a symposium paper published by Heid in 1983 and the annual reports of the Registry.

from all causes was determined for workers principally at Hanford and at Oak Ridge. Since the Hanford group included plutonium workers, it could be imagined that this study might have a bearing on validation of the plutonium standard. It did not, because the measures of radiation dose were from film badges, thermoluminescent dosimeters, etc., and thus were confined to external radiation sources. Indeed, it is difficult to ascertain whether or not the possibility of an internal dose was factored into the study even though its presence could influence the results. In some reports it appears that it was, in others that it was not.

We should probably drop the subject here. However, the results have been quite controversial and we feel duty-bound to help the reader find more. Mancuso stormed off the project with charges of bias and suppression of information by the sponsors. Others joined the fray, and much of the potential benefit of an objective analysis became difficult to achieve. Samples of the publications with special bearing on Hanford are as follows: Mancuso, Stewart, and Kneale 1977; Gilbert and Marks 1979a,b; Kneale, Stewart, and Mancuso 1979a,b; Gofman 1979; Tait 1979; Hutchinson et al. 1979; Kneale 1981; Kneale, Mancuso, and Stewart 1981; Spiegler 1981; Gofman 1981b; Tolley et al. 1983; Kneale, Mancuso, and Stewart 1984; Gilbert and Petersen 1985. Of these, the Gilbert and Marks paper in *Radiation Research* is a full presentation that refers to earlier full treatises. Many of the others are exchanges of letters. Gofman gives detail, including an analysis of his own in his book (1981a).

7. Validated?

On balance, the enormous efforts detailed above can be said to prove that there are no terrible mistakes in either the metabolic models or the basic standards for plutonium based on effects or projected effects. A factor of two, even somewhat more, must be considered within experimental error in so complex an enterprise. Furthermore, the work points strongly to handling each case as a separate entity.

The USTR has served well so far in validating the basic features of the models. But it has turned up many differences in detail. These have been (and are being) used to modify the models via the computer codes.^(a)

In chapter 9, we reviewed the "Hot Particle" problem as applied to depositions of plutonium in lungs. There is little possibility that the standards could be high by the enormous factors postulated therein. The validation process described above would have surely revealed a mistake of this magnitude. Yet, as detailed in chapter 9, we are still not sure about the significant area (or volume) and therefore the significant dose to lung. (See also Stannard 1975, where the effect of changes in metabolic models, critical tissue, critical tissue weight or volume, etc. on derived levels for ^{238}Pu and ^{239}Pu are described.)

Morgan (1975) proposed a reduction in permissible exposure to plutonium and other transuranic elements by a factor of two hundred. This was derived by a series of factors for (1) increase of the n factor from five to fifteen on the basis of the Utah dog work, (2) difference in the surface-to-volume ratio of bone in man compared to dog, (3) difference in rate of turnover of radionuclides in bone of dog compared to man, (4) relative sensitivity of baboon versus dog, and (5) a general feeling that the linear hypothesis for dose-response relationships

(a) Ford et al. (Oak Ridge) began the process of modification in 1978.

may not be sufficiently conservative. The validation process described above for plutonium should surely have turned up a factor of two hundred too high. The only reservation is that the group size is still small. Final conclusions hang upon the large study involving over twenty thousand subjects, which will require many years for completion.

Two recent additions to the literature on the actinides contribute further to the subject at hand. The first is an International Conference on the Radiobiology of Radium and the Actinides in Man, published as a supplement to *Health Physics* (Rundo, Failla, and Schlenker 1983). The second is a gathering in a special issue of the same journal of a series of papers on the 1976 americium exposure incident (Thompson 1983). Both of these provide more new information on incidents and research than on the validity of standards, but they are important nevertheless to this review.

B. Validation of Uranium Limits

The story for uranium is quite different from that for plutonium. Even quite early there was evidence of discrepancies between predicted body and organ burdens and the actual; and evidence of marked differences between animals and humans in the chemical toxicity of uranium. Despite these facts and the fact that the uranium worker population was one of the largest in the World War II years and in the decade of the 1950s, the amount of follow-up was pitifully inadequate for several decades. In this section, we will examine the early studies first and then the more recent efforts to catch up before it is too late.

1. Earlier Findings

In chapter 2, we reviewed the work done with patients at Rochester during the war and at Boston, Oak Ridge, and Rochester in the early postwar years. These were in part validations of the older metabolic data for humans and the growing fund of information from animals.^(a) The information from this work was used as much to establish new facts and metabolic constants as for validation of what had been for man a modest collection of data.^(b)

Hundreds of employees of the various companies processing uranium to produce nuclear-grade uranium metal and compounds were exposed to dusts and fumes of the metal. Only a few of the processes were "wet," most were dry and very dusty. With some exceptions that we will note later, industrial hygiene measurements and control in the war years were primitive or absent altogether. In the early postwar years, the New York Operations Office of the AEC undertook systematic industrial hygiene measurements of all uranium processing establishments; concentrating on airborne dust. The lung model of the day (see section VI A) was used to predict lung content, and the then-current metabolic model was used to compute amounts in other tissues. These were based largely on experience in dogs. The story is told in fascinating style by Merrill Eisenbud, who was director for many years of the AEC Health and Safety Laboratory in New York. Tissues from two men who died of nonoccupational causes but who had long histories of exposure to high concentrations of uranium dust yielded

(a) All important references have been cited either in chapter 2 or earlier in this chapter.

(b) Use of the Boston experiment as a therapeutic modality is taken up in chapter 20. See also Hursh and Spoor (1973).

measured amounts startlingly less than predicted (0.35 $\mu\text{g/g}$ measured versus 600 $\mu\text{g/g}$ predicted in lung for one case and 0.23 versus 56 in the other case). This began the process. Case after case came in with the same picture (Eisenbud and Quigley 1956; Eisenbud 1975). The agreement between predicted and observed values was much better for bone.

Urinary excretion was so erratic that little could be done to compare measured and predicted amounts in a given individual. However, the individual differences had much less influence when averages of many individuals were used. In fact, Eisenbud and Quigley note that conclusions regarding the amount of uranium excreted in urine in persons exposed to the (MPC)_a of uranium was in "excellent agreement with the predictions of Neuman based on animal data" (Neuman 1950).

The chief problem for validation of the metabolic models seems to lie in the lung deposition figures. Eisenbud gives a possible explanation. The predicted alveolar deposition was based on particles of unit mass. Uranium dust is so very much heavier that the 2- μm particles assumed to deposit in alveoli probably never got beyond the nasopharynx.

The second discrepancy was in the effects produced. Exposures were very high in some of the World War II plants (Eisenbud 1975). Some were recorded at two hundred times the permissible air level, but this probably included considerable nonrespirable dust. Nevertheless, the chemical toxicity noted in the animal work predicted a rash of kidney problems in these workers. There were cases of albumin and casts in the urine, as we have seen, but little else.

Let us review the situation in the forceful language used by Merrill Eisenbud under the heading, "The Need for Epidemiological Follow-up."

The Manhattan District during World War II was of necessity a highly compartmentalized organization in which investigations were carried on at a frenetic pace and in many cases without the opportunity for the kind of exchange of information that one normally expects in the scientific community. The pharmacological and toxicological properties of uranium were investigated mainly at the University of Rochester under the direction of Dr. Harold Hodge and his very able staff. The studies conducted at Rochester were published in 1949 as part of the National Nuclear Energy Series in four volumes that totalled nearly 2500 pages. In contrast, there were essentially no wartime data on the levels of exposure that existed in the various plants, and there was essentially no medical surveillance of these employees. With the formation of the Atomic Energy Commission, and the New York Operations Office, systematic studies began in late 1947 and continued until the shutdown of the old plants by about 1954.

In 1955, the first United Nations Conference on the Peaceful Uses of Atomic Energy was held in Geneva, and the United States' contribution included two major presentations on the toxicology of uranium. The writer, in association with Joseph Quigley and others of the HASL team, summarized the results of the studies that had been conducted up to that time. With respect to chemical toxicity, the conclusions of this paper were very different from the report from Rochester, which was based on findings in animals:

"There has been sufficient experience with severe exposures to both soluble and insoluble compounds of uranium to permit the conclusion that uranium has a low order of chemical toxicity in man. Many of the nonradioactive heavy metals, such as lead, arsenic, and mercury, would produce very severe, perhaps fatal, injury at the levels of exposures reported here." (from HASL).

"Uranium is one of the most toxic elements chemically, more toxic than arsenic or mercury." (from Rochester).

At the 1958 conference^(a) on the health experience of the uranium industry, Mont Mason stated that there was no demonstrable damage to any employee due to chronic uranium exposure. Considering the high exposures of the past, Mason added: "We are not at all smug about this—only grateful." This was also the conclusion of the HASL group. So far as the chemical toxicity of uranium is concerned, we are fortunate indeed that man is less susceptible than the laboratory animals.

However, this statement could be made with more confidence if there had been more thorough follow-up of those who worked in the early production plants. I was disappointed while preparing this paper to find that there had been so little additional information accumulated since 1955.

(From Eisenbud 1975, pp. 13-14, references deleted.)

Eisenbud concluded his paper with the following: "There is reason to believe, based on the few human data that do exist that the chemical toxicity of uranium (in man) is far less than was anticipated. . . . While this is reassuring, the cases are too few to constitute any more than highly equivocal evidence. The laboratory evidence from the University of Rochester leads one to conclude that uranium is highly toxic. The field studies suggest the contrary. Only epidemiological follow-up of the uranium workers can produce the information we need." (Eisenbud 1975, p. 15)

Eisenbud also notes that the literature on animal toxicity and mechanistic studies approached three thousand or more pages, while the epidemiologic literature for the same period did not exceed twenty-five pages!

Actually there was more stirring toward epidemiology than Eisenbud implies. It happened that Eisenbud's presentation came close to the very beginning of the 1975 conference. Later, there were full sessions with reports aimed at finding effects by representatives from ore processing mills, uranium refineries, a fuel fabrication operation, and the Oak Ridge Gaseous Diffusion Plant. Furthermore, representatives of the NRC and ERDA reported their occupational experiences, and there was a review of cancer mortality in uranium mill workers.^(b) (See also Archer, Wagoner, and Lundin 1973.) It must be admitted that none of these were formal epidemiologic studies, nor was there any sign of coordination among the contractors or in Headquarters to make full use of the information. This, while better than nothing, did not give the impression that the investigators were really trying very hard to follow up. The lack of effects in the early studies seems to have discouraged such an effort.

Asher Finkel, whom we met in chapter 1 when he was associated with the Argonne Radium Project and who had meanwhile assumed responsibility for occupational medicine in the American Medical Association, asked, as part of a panel discussion at the 1975 meeting, "Why isn't there a uranium registry? Why is the transuranic element registry so unwilling to take on uranium as an additional project?" (ERDA 1975, p. 352)^(c)

Some steps toward epidemiology were described at the 1975 conference. A study had been undertaken in 1962 by a group at the University of Colorado to determine the *feasibility* of conducting an epidemiologic investigation of the health of workers in a few typical uranium feed plants. This was headed by Dr. Robert F. Bell and has been identified as "The Bell Study." There were four

(a) A meeting on uranium in New York reviewed in USAEC Report HASL-58.

(b) The full program for this conference is shown as note 5 at the end of this chapter.

(c) The author of this book asked the same question at an advisory committee meeting of the USTR somewhat earlier. The answer was that funds were not available.

unpublished documents between 1962 and 1966 and a supplementary commentary by Joseph Quigley of National Lead Company in 1967. The conclusions were that the information desired *could* be obtained, i.e., such a study was feasible. Dr. Quigley even recommended that a full-scale study be undertaken. This development was reviewed by Sidney Marks, then at ERDA Headquarters, at the 1975 conference (Marks 1975). Subsequent to the Bell Study, it was decided to include the uranium feed plants in the ERDA Health and Mortality Study conducted by Dr. Thomas Mancuso at the University of Pittsburgh.

The overall cancer rate for the plant studied most thoroughly was not significantly different from that in the community. Why do they not talk about kidney damage? The fact is that little evidence was found for it. Why?

Remember from chapter 2 and the Hursh-Spoor reviews cited earlier in this chapter that the chemical toxicity of uranium seen in the animal experiments is very dependent on the dosage regime. Tolerance can develop quickly and significantly when a series of small doses precedes a larger dose. There is reason to believe this occurs in man also. Therefore, the lack of evidence for kidney damage in the long-term plant experience may rest upon the phenomena of tolerance. Obviously, the difference between humans and animals may represent more than this, but it is a factor that must be considered in any serious epidemiologic study.

The animal experiments of the 1950s and 1960s were, of course, essential to the building of the models in the first place.

2. Other Developments in the 1970s

Undoubtedly, one reason for the lack of interest in validation work for uranium was the marked decrease in processing of uranium. With the development of plans for new fuel cycles in the early 1970s, including a possible uranium-thorium cycle, interest appears to have been heightened. The Energy Research and Development Administration produced a bibliography on Occupational Health Aspects of Uranium, citing one hundred references in the period 1971 to 1974.^(a) Many of the cited references concern urinalysis, bioassay, in-vivo measurements in lung, tissue contents, and basic biochemical behavior. About half are from countries other than the United States. However, there is, as Eisenbud stated, little epidemiology. One paper, from Oak Ridge, discussed mortality experience of uranium compared to nonuranium workers (Scott et al. 1972), and another by Archer and colleagues (1973) considered cancer mortality in uranium mill workers. Although it was not a full-fledged epidemiologic study, the results were interesting. The mortality experience was more favorable for the uranium workers than for the nonuranium workers in the same plant.^(b)

An important development of the early 1970s pertinent to validation of the uranium figures came from the U.K. Atomic Energy Authority. Donoghue et al. (1972) analyzed tissues from a uranium worker of ten-years' standing who died suddenly from natural causes. Quite complete airborne dust and urine sampling had been carried out. The concentrations ($\mu\text{g U/g wet tissue}$) were 1.2, 1.8, 0.09, and 0.14 for lungs, lymph nodes, sternum, and kidneys, respectively. These amounts are less than 1% of the amounts calculated from the environmental

(a) This was called "preliminary," but I have not found a later version.

(b) Note this was *not* during the period of "dirty" operations.

data! In agreement with the ideas expressed by Eisenbud regarding deposition of uranium dust, a large proportion of the inhaled dust was deposited in the nasopharynx.

The authors suggest possible explanations for the low deposition: (1) pulmonary clearance processes for insoluble uranium dust may be very much faster than the ICRP's 360-day half-life would predict, or (2) deposition is indeed much smaller than the models predict. They favor the second alternative because of the quite small amounts found in urine, again far below the model predictions.

Donoghue et al. give a fairly complete history of work prior to about 1971 on the pharmacokinetics of uranium in the human respiratory tract. Their table is reproduced below as table 16.7A, which gives also some of the results. In table 16.7B, amounts of uranium in lung, kidney, bone, and liver of exposed and unexposed human subjects are given. The important conference sponsored by ERDA on uranium problems has already been cited (ERDA 1975, Hursh 1975).

TABLE 16.7A. Human Metabolism of Insoluble Uranium

Investigator	Place	No. of Exposed Persons	Chest Burden		Biological Half-Life (days)	Substance
			mg	nCi

Note: The original references for this table are not given here. Most, except Meichen, have appeared in this book (see author index).

3. The U.S. Uranium Registry

In 1978, at long last, a U.S. Uranium Registry (USUR) was organized by ERDA. Funding was provided by ERDA and continued by its successor, DOE; and it was placed under HEHF along with the Transuranium Registry. It was described by Marks at the Snowbird Actinide Symposium (Marks 1981).

The major goals of the Registry were stated as:

1. to characterize the front end of the uranium fuel cycle for electrical power production;
2. to do a feasibility study on establishing a centralized registry of all uranium workers; and
3. to establish a voluntary tissue donation program patterned after the successful USTR.

The inclusion of the entire uranium fuel cycle meant that the uranium miners came under its umbrella. Note also that, while the USUR is primarily an autopsy program like the USTR, there is a potential for identification of populations for epidemiologic study, presumably to be done by someone else.

The staff and management are shared with the USTR, but there is a separate director, Dr. Robert H. Moore, and an identifiable program.

The first report was a field study of the commercial fuel cycle and was published in April 1981. This was primarily to identify processes and sites and to begin the process of getting permission for autopsies, etc. The second report concerned uranium and hard-rock miners.

It is regrettable that the Registry was founded so long after the days of serious overexposures. However, the population is large enough that meaningful results may still be possible. The work is progressing actively.

The personnel for the Uranium Registry are all part time by sharing with the Transuranium Registry (see previous listing) or with other units in the Richland complex, principally PNL.

The personnel most identified with uranium problems (as of 1985) are:

Bryce D. Breitenstein, Jr., M.D., President, HEHF
 Scott E. Dietert, M.D., Manager, Research, HEHF
 Robert H. Moore, M.D., Director, USUR
 Ronald Kathren, consultant, Battelle Pacific Northwest Laboratory
 (now full-time with HEHF)
 Patricia Blackburn, C.P.S., secretary

Note that the Advisory Committee named on page 1471 serves both the Transuranium and the Uranium Registry.

Dr. James McInroy, at Los Alamos, and Dr. Robert W. Bistline, at Rocky Flats, coordinate the bulk of the analytical data for both registries. While they are not officially employed by the registries, their contributions to, and interrelationship with, the enterprise are enormous.

4. The Oak Ridge Epidemiologic Studies

The Medical Division of the Oak Ridge Associated Universities (ORAU) has undertaken a formal study of the World War II uranium worker populations. This was apparently stimulated and guided in its initial stages by Clarence Lushbaugh, a pathologist who spent many years at Los Alamos and who has been much in demand for the many hearings of the past decades. This study considered first a total of about forty-five thousand persons estimated to have worked at the Tennessee Eastman Corporation (TEC), a subsidiary of the Eastman Kodak Company, which operated the Oak Ridge Y-12 plant from June 1943 to May 1947.^(a)

The official reasons given for selecting the TEC group were: (1) long period of follow-up; (2) availability of data in the final year or so on average levels of uranium dust in air, including high levels in some operations; and (3) large sample size.

The first report was a study of mortality prepared by A. P. Polednak and E. L. Frome. It was presented at a DOE statistics symposium at Gatlinburg, Tennessee, in October 1979 and published in 1981 (Polednak and Frome 1981). They used records of the Social Security Administration and standardized mortality ratios (SMR) for various causes of death. The SMR values were generally less than 1.00, i.e., less mortality than in the general population. This was attributed to the "healthy worker" effect. However, after correction for unascertained deaths and missing death certificates, the SMR for lung cancer in the entire cohort was 1.22, with confidence limits (95%) from 1.10 to 1.36. However, neither this nor other SMR values was higher in the more than eight thousand workers who had contact

(a) This author was personally delighted to see that this population had been selected. His implicit faith in the competence, good judgment, and appreciation of future needs by Dr. James Sterner, who was medical director of TEC, made it seem likely that the industrial hygiene would have been better than average for the day and the medical records good enough for retrospective epidemiology, assuming they were preserved.

with uranium compared to others who did not. Leukemia, bone cancer, and respiratory and urogenital tract dyscrasias did not have elevated SMR values.

The air sampling data and methods of the final years are given in detail, including both particle-size distributions and the specific activity of the particles, important since this was an enrichment process. There is also a summary of urinalysis records. However, no comparison is made between predicted urinary uranium and actual.

Some calculations are made of possible radiation dose to the lungs from exposure to 150 μg insoluble natural uranium per cubic meter.^(a) These were 125 rem after one year of exposure, 30 rem after a ten-week exposure, not insignificant.

The elevated lung cancer incidence was confined to "alpha chemistry workers" hired at age forty-five or later. The data are complicated by the presence of chemically toxic substances such as phosgene, solvents, mercury, etc.; by the usual problems of using the diagnosis placed on a death certificate; and the fact that the study is far from complete.

Little mention is made of kidney pathology, kidney function disorders, or diseases of the circulatory system (which might be expected from chronic kidney damage). In fact, the SMR values are considerably less than one for diseases of the genitourinary system and for diseases of the circulatory system. These values were greater than one only for electrical workers (181 cases out of 1,172 workers). Obviously, this study provides an excellent start but no startling surprises.^(b)

The second major contribution from this study zeros in on the lung cancer picture. In a paper delivered at the 1983 Mid-Year Topical Symposium of the Health Physics Society, Diane Cookfair, at the time of the work a doctoral candidate in epidemiology at the University of North Carolina at Chapel Hill (Cookfair et al. 1983),^(c) examined cases and controls from 19,412 TEC employees. There were 330 cases of fatal lung cancer in the cohort between 1943 and July 1973. Age and smoking status were given particular emphasis.

A statistically significant excess in risk for men over age forty-five when first exposed appeared with calculated lung doses of 20 rad or more (200 to 400 rem depending on whether the old or the new Quality Factor is used). The broad results are shown in table 16.8.

There seems little doubt of the age effect. The effect did not seem to be greatly different in the smokers, except for the high-dose (20 to 74 rad)^(d) group, where the odds ratio was 8.62 for cases versus deceased controls and 11.60 for cases versus live controls. The study concludes that older age groups may be more susceptible to radiation-induced lung cancer.

(a) Remember that the permissible air levels were in the range of 200 $\mu\text{g}/\text{m}^3$.

(b) The travail behind the scenes for mounting such a study is seldom appreciated. For many years, a storage room on the roof of the University of Rochester Atomic Energy Project contained rows of old wooden files with cards concerning MED workers. When a third story was put on the building, the card collection was almost thrown out. Fortunately, it was shifted to Oak Ridge, where it was transferred to computer tapes. Clarence Lushbaugh had the task of determining to which operation a given card pertained and gradually assembling the TEC workers. This was presumably added to records already in Oak Ridge. Other populations await study.

(c) Dr. Cookfair is now on the staff of the Roswell Park Memorial Institute, Buffalo, New York.

(d) A separate paper from the Oak Ridge group described the radiation dosimetry for lung (Beck et al. 1983).

TABLE 16.8. Cumulative Lung Dose Odds Ratios from the Stratified Analysis by Level of Exposure and Hire Age, Smokers Only

Level of Exposure*	Cases Vs. Deceased Controls		Cases Vs. Live Controls	
Hire Age <45	OR (95% CI)**		OR (95% CI)	
Low	0.78	(0.35, 1.72)	0.30	(0.15, 0.61)
Medium	0.39	(0.16, 0.96)	0.19	(0.08, 0.43)
High	0.57	(0.26, 1.25)	0.55	(0.23, 1.28)
Hire Age ≥45				
Low	1.64	(0.50, 5.34)	1.23	(0.35, 4.38)
Medium	1.23	(0.07, 21.00)	0.26	(0.03, 2.37)
High	8.62	(1.32, 56.40)	11.60	(1.04, 130.00)

*Low: 0.001 - 5 rads; Medium: 5.001 - 20 rads; High: 20.001 - 75 rads

**CI = Confidence Interval ($\alpha = 0.05$)

Source: Reset from Cookfair et al. 1983.

Note again the absence of commentary on kidney or circulatory changes. Even though the study focused on lung cancer, any serious problems in these areas should have become evident.^(a) Oak Ridge Associated Universities is continuing analysis of this and other populations of workers. The results are still coming in but are beyond the nominal cutoff time for that history. Suffice it to say that there have not been notable surprises. It is truly unfortunate that the information on exposure is so much less complete than that on the health of the workers. Really adequate air concentration measurements were a very late addition to routine operations.

The ORAU-sponsored study and other research should soon provide analyses for worker populations in other uranium processing plants. Future publications will be awaited with considerable interest.

5. Validated?

The early returns indicated serious problems with some of the metabolic constants for uranium, especially those for the respiratory tract and an apparently marked difference in susceptibility of humans compared to animals in the nephrotoxic action of uranium. These differences persist. Possible explanation for the much lower than expected deposition in lung lies in the high density of uranium particles (Eisenbud). Possible reasons for the paucity of findings of kidney damage in humans may lie in the phenomena of developing tolerance to uranium effects, but this is only conjecture.

It cannot be said that recent work has proven these explanations to be fully correct, but it is on the way. On the metabolic side, an entirely new model for uranium has been constructed (see Wrenn 1981; Wrenn, Roswell, and Durbin 1982; Wrenn et al. 1985; Durbin 1986). This involves changes in much more than

(a) One wonders why the study of this important group had to wait so long to begin. In answer to a question from the author, Dr. Cookfair responded that the data could not be released until the processes involved had been changed.

the respiratory-tract deposition constants. Only the future can tell whether or not subsequent autopsy data will confirm the new model. We will look to the USUR for this.

Despite Eisenbud's dramatic story on difference in chemical toxicity between humans and animals, few if any of the current studies are looking very carefully at chemical toxicity of uranium in different species. The emphasis has shifted to correlation with radiation dose, as described in chapter 15 for drinking water standards. The continuation of studies at Oak Ridge and new populations that USUR may identify is needed to nail this down. Meanwhile, it appears that Mont Mason's remark (quoted by Eisenbud [1975]), "We are not at all smug about this—only grateful," seems to characterize the present views toward nephrotoxicity.^(a)

On balance, we must conclude that none of the evidence indicates that the basic standards for exposure to uranium are seriously wide of the mark. There are more puzzling inconsistencies, however, than for many other standards. While reasonable explanations are forthcoming, there is no way to prove retrospectively whether or not they are correct. It will require very carefully planned and executed epidemiologic studies to settle conclusively some of the remaining questions, and these must be done while the exposed populations are still with us.

C. The Fission Products

Most of the work involving the fission products has already been reviewed in chapter 13 since the *raison d'être* was fallout from weapons testing, as well as in chapters 6 and 8. Some of the research is of more or less general applicability to the validation of standards. Some was reviewed in chapter 13 and should be consulted for completeness.

1. Strontium

The isotopes of strontium important to people, ^{89}Sr and ^{90}Sr - ^{90}Y , have been studied in humans primarily by using the convenient short half-life isotope ^{89}Sr . These are exclusively metabolic rather than effects studies, since the doses were all at tracer levels. Nearly all of the work has been since World War II. A large share of the work has emanated from laboratories abroad rather than from those in the United States, except for measurements connected with fallout. A notable exception is the work done by Herta Spencer at the Hines Veterans Hospital in Hines, Illinois, begun by Laszlo and Spencer at the Montefiore Hospital in New York. We will consider it first.

Much of Spencer's work concerned therapeutic removal of alkaline earth metals by chelation. Therefore, a fairly complete bibliography and the substance of the experiments are reserved for chapter 19. We will review here a few of the basic findings.

A useful review by Spencer and colleagues of the ^{89}Sr method and the effects of manipulation of dietary factors, including stable strontium concentration and

(a) Note added in proof: In 1982, Paul Morrow at Rochester completed a study for the NRC that indicated a potential need for lowering the threshold concentration for kidney damage below the current $3\text{ }\mu\text{g/g}$ (Morrow et al. 1982). Since the experiments did not produce steady-state levels, further evaluation is required.

of some hormonal factors, is contained in the *Proceedings of the International Symposium on Some Aspects of Strontium Metabolism* (Lenihan, Loutit, and Martin 1967).

First, the absorption (Spencer, Lewin, and Samachson 1967) was calculated from plasma levels and fecal excretion. The two agreed reasonably well. The average absorption varied among twelve patients from about 35% to about 10%. The authors state the average true absorption of an oral dose is 20%, with 80% unabsorbed and 2.5% passed in the stool as endogenous excretion of ^{85}Sr . The fraction from gastrointestinal tract to blood for all strontium isotopes was given in the ICRP/NCRP 1959 reports as 0.3 (30%). The same value is adopted for soluble salts of strontium in ICRP Publication 30, Part I (1979) but with a reduction to 0.01 (1%) for strontium titanate. Publication 30 gives a range of 0.2 to 0.5 for uptake of soluble salts. No serious problems of validation appear here, especially since the recommended value is higher than that found experimentally in humans by Spencer et al.

Second, the effect of adding stable strontium was to raise the plasma levels of ^{85}Sr . This indicated greater absorption of ^{85}Sr in the presence of stable strontium. If this is a mass effect, it is the opposite of that seen for uranium (see section VI B).

The balance of the review concerns the influence of the many dietary and hormonal factors. There is no doubt but these can play an important role. Any model made for one set of circumstances can be significantly wrong in other circumstances.

At the same symposium, Cyril Comar stressed the need for always paralleling strontium measurements with measurements of calcium. This was reviewed in chapter 13 (Comar 1967). Spencer's work was laced liberally with studies of calcium concentrations and behavior.

Several other U.S. studies in humans are quoted by Comar and Wasserman (1956). They include work from Comar's group and earlier work of Laszlo and Spencer. These include effects of disease processes. The only work with direct bearing on validation concerns the possibility of estimating initial body burden from subsequent excretion curves.

A tenet of the animal work was that strontium remained only briefly in soft tissue and was deposited primarily in bone for any periods beyond a few days. Was this validated in the work with humans? Work from the United Kingdom and other work by Spencer quoted in chapter 19 bears on this question.

Rundo (1967), then at Harwell, measured the retention of ^{85}Sr in the skeletons of two subjects maintained for twenty-one to thirty-two days on a constant diet containing the isotope. He was able to measure skeletal content by in-vivo techniques even when considerable strontium was still in the gastrointestinal tract. From about five days after cessation of intake, virtually all of the strontium was in the skeleton.

The retention function for skeleton as Rundo developed it had three exponential components, which described the retention better than the single component model of ICRP/NCRP. ICRP Publication 30 uses the Marshall model (see section V B), a somewhat more complex representation but not widely different. As usual, a power function could also fit the retention data, as we have seen many times before for other radionuclides. Rundo discards it because it "has no physiological significance."

At the same international meeting, Harrison and Sutton (1967) from the Medical Research Council facility at Harwell presented data on the ratio of fecal

to urinary clearance of strontium in humans. The subjects showed individual differences in the ratio after ingestion in the diet compared to intravenous doses.

Lloyd (1967) found lower renal clearance and less strontium/calcium discrimination in the rabbit than in people.

It can be said that the basic premise that most of long-retained strontium is in bone has been validated in humans. The species differences, variations among human subjects, mode of representation of retention functions, etc., do not invalidate the basic models; but they point to the need for continual updating of models when assessment is needed and the use of data from the individual concerned rather than blanket models designed for the prospective setting of standards.^(a)

In an earlier section of this chapter, we quoted recent work from the University of California at Davis where dose-response relationships for ^{90}Sr and ^{226}Ra were compared in several species, including humans. These, as well as the Utah research, go far toward showing the degree to which the results of long-term animal experiments can be applied to man, in other words their validation vis-à-vis man. It is broadly satisfying but full of differences in detail.

While the coverage above is not complete, it should suffice to show that no large problems have appeared concerning validation of the data for strontium in humans, but they apply only to its metabolism. Thankfully, no exposures to humans have even approached those at which effects would be expected.

2. Iodine

Most of the research with radioiodine has concerned either its uses in medicine or environmental contamination problems. The former appears in chapter 20; the latter has already been discussed in chapters 9, 10, and 13.

There is no question about iodine concentrating almost exclusively in the thyroid in humans as it does in animals. The biological and effective half-lives have been tied down by innumerable clinical measurements.

The largest problem with validation of the old standards for iodine came in terms of environmental transport and population exposure standards. As we saw earlier, the practice used by both the advisors (see section II A) and the regulators (e.g., The Code of Federal Regulations) was to devise population standards by use of a scaling factor from the occupational standard. Careful analysis of the plant-food-cow-milk-human chain done as part of the research stimulated by fallout showed that the standard scaling factor was totally inapplicable to populations exposed to iodine through this chain. This led, as described earlier, to reduction of the allowable discharges of iodine by a factor of seven hundred (rounded off to one thousand). Research in man played only a small part in this process. However, the entire chain could be said to have been a part of the validation of the old standard.

D. Other Radionuclides

Data on humans useful for validation of standards are not numerous for radionuclides outside of the three major classes discussed so far in this section—

(a) Unfortunately, the current regulatory climate tends to inhibit the application of idiosyncratic data, even though it may be scientifically justifiable and technically impeccable.

actinides, uranium, and fission products. The exception is the gaseous elements like tritium, the noble gases, etc.

Because of its importance in both fission and fusion, tritium has received some attention that might be called "validation." One example is work by Osborne (1972) at the Chalk River installation of Atomic Energy of Canada, Ltd. Osborne considers the physiology of tritium, the types of exposure, and the pertinent parameters to determination of permissible levels. He overtly compares the experimentally determined parameters with the ICRP/NCRP (1959) parameters and calculations. He reviews most of the considerations we saw in chapter 10. The role of the tritium bound to tissue components receives special attention, as it should.

Osborne concludes that current limiting levels in air, drinking water, and food, as well as the choice of body water as the critical tissue, are all conservative. He does not indicate *how* conservative. Apropos the nagging problem of tritium in DNA, he estimates (along with others we have met in chapter 10 and will in chapter 20) that less than 0.2% of the initial dose rate to the nucleus is from tritium in DNA, and the annual genetic dose is about 0.3 mrem. Thus, it appears that once we took account of skin absorption of tritium (chapter 10), the standards for tritium had been validated amply.

Validation of the original standards can be viewed as reasonably good for the noble gases as well, as emphasized by Osborne for tritium. Information is still needed on other substances, particularly environmental transport parameters.

A final bit of validation concerns barium. Research by Newton, Rundo, and Harrison (1977) at the AERE, Harwell found good support for the ICRP alkaline earth model (The Marshall model) using data on ^{133}Ba in a sixty-year old man.

Space prohibits further exploration of this type of work. The nature of the research, its locales, and the extent of validation should be clear from what has been said.

VIII. Epilogue

There is little doubt that the research information developed for radionuclides played an important part in the development of standards for limiting exposure. The mere bulk of this chapter should testify to that. Nor can it be denied that large portions of the experimental work had as an ultimate, frequently a primary, goal the development of information applicable to the standard-setting process. The standard for ^{226}Ra was as closely coupled to overt experience of effects in humans as any radiation standard we have. The complex computational schemes and the many models were entirely dependent upon the metabolic data produced in the researches we have reviewed. Need we say more? I am afraid we must.

As discussed briefly in earlier parts of this chapter, the standard-setting process has many facets. It inevitably involves judgment, selection, and many factors totally outside of biology and medicine. Even the radium standard involved judgment by using a factor of ten below the body burden at which effects first appeared and the subjective decision as to whether or not one would be content to have his own wife or daughter carry a burden of $0.1\ \mu\text{Ci}$ of ^{226}Ra . The selection of metabolic factors always required a judgment. As discussed earlier in the chapter, selections were made for a "best" figure for the situation at hand. They were not averages or any other statistically based figure.

When we depart from the radium standard as a base, the primary standards for radionuclide exposure have been based upon the maximum permissible dose of external radiation. This was selected in a highly judgmental manner. It is difficult to trace the exact steps leading to its selection. Although it has served us well, it would be a gross overstatement to indicate that it had been derived by a purely scientific process starting from first principles.

A most interesting analysis of the history of radiation protection before World War II was developed by Daniel P. Serwer at Brookhaven National Laboratory under the title "BEAG" (Serwer 1976). The report analyzes the role of social pressures, professional groups, and to a lesser extent economic factors in the practices of radiation protection in the period discussed. Unfortunately, science comes out second best for the primary standards.

This phenomenon is not limited, of course, to radiation standards. Purely scientific facts were given an even less central role in most of the early standards for chemical toxins than Serwer concludes is true for radiation standards. Nevertheless, it was the scientific information that began the process. It just got mixed in with many other processes along the way.

As our ideas of what is acceptable have urged even lower standards, and as the linear no-threshold concept took over the thinking and implied that there was no completely "safe" dose, the role of the purely scientific process has become even more difficult. Indeed, it seems unlikely that there could ever be a scientific experiment or process of sufficient size or complexity to determine quantitatively the effects on populations of the very low radiation doses now being considered as potential limits. As the uncertainty rose, so did the controversy and the opportunity for nonscientific aspects to assume control.

Recently, Crandall and Lave have edited a book prepared by the Brookings Institution in Washington entitled, *The Scientific Basis of Health and Safety Regulations* (Crandall and Lave 1981). This is not aimed at radiation regulation, but the processes chosen are comparable. Using five case studies and expert groups to comment on each, they conclude that scientific data and their analysis now play a minor role in the setting of primary standards. In a scathing indictment of some of the regulators, the following appears "... An agency may exacerbate concern about a trivial or non-existent problem ... Standards are enacted on the basis of only fragmentary evidence of a potential Health or Safety Hazard. ..." (From Thomas's 1983 review of the Crandall and Lave book).

Does this mean we have been wasting our time and resources? It does not! First, the fund of scientific information in the radiation field far exceeds any other. We have the best chance of having pertinent scientific facts. Second, it is only in the setting of the *primary* standard that the nonscientific aspects enter. Once that is established, the myriad computations and models for radionuclides in both humans and the environment must be brought into action. The scientific and technical data are absolutely essential for these; they will continue to be.

Currently there is a strong tendency to base standards on risk rather than dose. To do this, the conventional dose-response curves have been translated into dose-risk curves. But this usually still requires calculation of dose and knowledge of radionuclide behavior. A pure risk approach, i.e., one that goes directly from intake or body burden to risk, is much to be desired. It is possible to do this for a few radionuclides, e.g., ^{226}Ra . As research continues, it may be possible for more. However, the time is far off when standards for all radionuclides can be determined without the intermediary steps of dosage calculation.

One important area that has been somewhat neglected until recently is one that is basic to the application of a primary radiation standard derived from experience with external radiation to those for radionuclides. Does a given absorbed dose have the same effectiveness, i.e., produce the same risk, whether delivered by x-ray photons or a deposited beta-emitting radionuclide? Broadly speaking they should be. An erg is an erg. But it is not so simple. Microdistribution of radionuclides and of radiation dose can enter the picture, as can other factors. A survey of this question by the NCRP committee cited earlier indicates already some possible exceptions, e.g., the longer-lived iodine isotopes. There may be more.

Finally, it will be noted that we have said relatively little about details of establishment of the primary standards for radiation exposure. These have been and are being competently dealt with by others. It should be obvious from the materials reviewed in this chapter, bona fide research of the most open kind, that radiation standards as they now exist have been broadly validated. It seems most unlikely that a large systematic error could have survived such careful scrutiny. No doubt there are many areas that need further work, but these are minor compared to the major unfinished business in the field of chemical toxicology and environmental pollution with toxic chemicals. Let us hope that the experience gained in setting radiation standards can be helpful in the enormous task we all face in this other arena. Let us hope, too, that perspective is maintained and radiation standards not reduced unduly by either scare tactics or a "because you can do it, you must do it" philosophy.

Important research is still needed for the development of still better standards for radionuclides, even though most of the standards have either been reasonably well validated, or reasonable explanations have been developed in the case of significant discrepancies. A system based upon direct estimation of risk is being explored by the NCRP.

IX. Summary and Commentary

This chapter reviews in a general way how the findings from the research laboratories and field experiences contributed to the process of setting limits for the intake of radioactive materials by humans. It is not a formal history of radiation protection standards. That has been and is being done very adequately by others. It does concern the use made of the information gained in the research programs, most of them reviewed in this book. In addition, there is discussion of those efforts made by the biomedical community toward validation of standards already set.

The organizations that now carry, or at some time carried, responsibility are detailed both for orientation and to highlight their contributions. The latter applies especially to the Tri-Partite Conferences on Internal Dosimetry held in the late 1940s and the work of the U.S. Federal Radiation Council. These, plus the many organizations still functioning, are listed with a short summary of the nature of their activities. All are considered as advisors, even some activities of the Congress of the United States. The regulators, state and federal, are also reviewed in broad terms.

Two quite separate systems have been used to arrive at standards for intake of radionuclides: (1) direct derivation from human experience modified by animal data and (2) computation of an intake limit based on a radiation dose

comparable to that allowed from external sources of radiation. Types of information and types of research applicable are quite different by the two methods.

The best example of direct derivation is the designation of the maximum permissible body burden of ^{226}Ra and calculated secondary standards for it. For this, the accumulated information from human experience, the radium dial painters and radium chemists and the patients that received radium as a therapeutic nostrum, led directly to a standard. Based on examination of records through 1940, it was determined that no significant health effects had been seen in individuals carrying body burdens of ^{226}Ra less than $1\ \mu\text{Ci}$. The standard became $0.1\ \mu\text{Ci}$ by insertion of a safety factor of ten, and it was promulgated in 1941. Although much more information has been accumulated in the intervening years, nothing has happened to question the validity of this first standard for a radionuclide.

The standard for ^{239}Pu was based on the radium standard. It used the ratio of effectiveness of ^{239}Pu to ^{226}Ra determined in the several experiments described in earlier chapters. It calculated a maximum permissible body burden by modifying the radium standard by the relative toxicity (relative effectiveness) ratio. This standard was developed during and at the end of World War II and has been strengthened by postwar research.

The first standard for ^{222}Rn was developed at the same time as the one for ^{226}Ra . It was comparable to most industrial hygiene standards in that it was based on measurements of air concentrations that, over long exposure periods, were not associated with demonstrable effects. Because of the short half-life of radon and its daughters, there was no way to determine corresponding body burdens. This standard was intended for application to work rooms. As described in chapter 3, the problems of radon exposure in mines required a more complex system whose genesis and characteristics are described there.

Exposure to natural uranium is another example of direct derivation. Only in this case it was a direct determination from the data obtained in animal exposures. The experiments are described in chapters 2 and 9. Despite the thousands of exposures of humans to natural uranium, it is too weakly radioactive to have produced, at the levels involved, obvious long-term radiation effects, and the evidence of chemical toxicity in workers has been evanescent. At the beginning, the uranium standard was linked by analogy to lead, but, as the animal work progressed, direct derivation was possible with, of course, suitable safety factors. As hinted at above, uranium exposures carry a dichotomy. With soluble compounds that are readily transported and excreted, chemical toxicity to the kidney tubules controls exposure. With very insoluble compounds, it can be calculated that radiation exposure might control. However, it took the heroic experiment described in chapter 2 to cram enough uranium into the lung and have it stay long enough to produce clear-cut radiation effects. None of the animal data used for deriving the earlier uranium standards showed anything but chemical toxicity.

A few other radionuclides can be considered to have had their standards derived directly from effects in humans or animals. Radium-224, the isotope of radium used in Germany over the period 1944 to 1951, generated data in humans sufficient to support a standard by comparison with ^{226}Ra . However, the use of ^{224}Ra was discontinued almost before this information could be generated, and it has been more useful for other purposes.

A final case of potential direct derivation is ^{232}Th in Thorotrast. As described in chapter 4, there is a large population of individuals who received Thorotrast

as a radiopaque medium, and this population is developing liver tumors. However, there were some complexities, and the operating standards for ^{232}Th were not derived directly. It now appears that the complexities have been solved, and we can look forward to future derivation of a thorium standard from the thorium organ burden in these populations.

The enormous expansion in the number of radionuclides to which people might be exposed required a different approach to standards—termed here the computational approach. There was obviously not enough information on effects for the majority of the newly developed radioactive materials to support direct derivation of standards. Instead, the maximum permissible dose rate to various organs, including the whole body, derived from experience with external radiation sources, was utilized. These had been developed from many years of experience with x and gamma rays and other radiation types from sources external to the body. This approach began officially at the Tri-Partite Conferences, but was in operation earlier in individual laboratories.

The accumulated metabolic information on a large number of radionuclides could be used for computing the dose to the target organ. Others could be computed by comparison to their chemical analogues. Reports were developed beginning in the 1950s giving a maximum permissible body burden, organ burden, and maximum allowable concentrations in air and water for hundreds of radionuclides. Recently, the ICRP has prepared a huge compendium listing secondary standards such as annual limits on intake, derived air concentrations, etc., for over seven hundred radionuclides. All of these are based upon the primary standard for external radiation exposure (the direct route was not used by ICRP in this latest version). In addition to physical characteristics, such as decay scheme and constants, biological retention in many organs, the relative concentrations in many organs, and general models for behavior in the lung and the gastrointestinal tract had to be determined and used. Thus, most of the enormous effort describing “metabolism” (i.e., pharmacokinetics) of radionuclides described in earlier chapters was brought to bear on the setting of standards. Details of the system and its variations and of the models are given in the chapter.

The converse of the use of the research data in setting standards is its utility in checking the validity of standards already set. Obviously, many standards had to be set with tenuous and preliminary information. The accumulated information from larger and longer-term efforts has been very useful in this validation process. The lack of demonstrable effects in humans from plutonium, uranium, strontium, and related radionuclides constitute, to a degree, a validation of the standards under which we have been working. However, the populations are small, and satisfactory epidemiology for many important elements is still in the future. The notable exception is ^{226}Ra , for which both the number and consistency of the follow-up cases can be viewed as ample validation of the original standard.

The large studies of lung cancer in uranium miners have provided both epidemiologic bases for the standards used and validation of some of the parameters used. Unfortunately, the problems of dose measurement and dose calculation have made the story more complex than for some other radioisotopes.

Another type of validation in man is seen in the several experiments with human subjects detailed in other chapters. These were metabolism experiments. The similarities of pharmacokinetics seen in humans to the much larger body of

information from animals can be regarded as validation for man of the use of the best of the data from animal studies.

Further validation of both standards and of various metabolic models and single parameters can be expected from the work of the U.S. Transuranium Registry and the U.S. Uranium Registry and the ongoing studies of the radium patients and the plutonium workers, plus a few new epidemiologic studies in populations exposed many years ago.

While it can be said that current data validate, in broad terms, the standards set and the important parameters of distribution, retention, and excretion, many details require clarification. Many models are very approximate. The validity of using the dose rate derived from external radiation sources for limiting internally deposited radionuclides depends upon there being no difference in effectiveness of a given dose under the different conditions. Only a few radionuclides have been examined critically in this regard with some, but not large, differences seen in certain cases.

Despite the ever-present needs for more information, it can be said that the researches described in this book played a key role in the derivation and/or implementation of standards for radioactive materials deposited in the body and their validation.

Note 1(a)

ICRP (1959) formulation for determination of the maximum permissible body burden (q) of radionuclides that deposit in bone:

$$q = \frac{q^{Ra} f_2^{Ra}}{f_2} \times \frac{\epsilon^{Ra}}{\epsilon} = \frac{0.1 (0.99)}{f_2} \times \frac{110}{\epsilon} = \frac{11}{f_2 \epsilon}$$

in which $q^{Ra} = 0.1 \mu\text{C}$ is the maximum permissible body burden of Ra^{226} ;

f_2 = fraction of radionuclide in the skeleton of that in the total body;

$f_2^{Ra} = 0.99$ is the value of f_2 for radium;

ϵ = effective absorbed energy per disintegration of a radionuclide = $\Sigma EF(RBE)n$; $\epsilon^{Ra} = 110$ is the value of ϵ for radium;

E = energy (MeV) deposited in skeleton per disintegration;

RBE = relative biological effectiveness = 1 for α , γ , β^- , β^+ , e^- , (it is set equal to 1.7 if the maximum energy, $E_m \leq 0.03$ MeV for β^- , β^+ or e^-), 10 for α and 20 for recoil atoms;

F = ratio of disintegrations of daughter to disintegrations of parent.

It is assumed that 99 per cent of the radium in the body is in the skeleton, and the total energy deposited in the skeleton per disintegration of Ra^{226} plus 30 per cent of its daughter products is 11 MeV, and thus the effective energy deposited in the skeleton is $\Sigma EF(RBE)n = 110$. For other radionuclides which are localized in the bone, the effective absorbed energy is found from $\Sigma EF(RBE)n$. (b)

(a) This approach and formulation were abandoned in the ICRP Report 30 (ICRP 1979). However, it was used for many years and is so important to the derivation of standards from the research data that we reproduce it anyway.

(b) As described elsewhere in this chapter, the value of n is taken as 1 if the radionuclide or its progenitor is an isotope of radium, as 5 for all other cases.

Note 2

ICRP (1959) formulation for calculating maximum permissible body burden (q) on the basis of the permissible dose rate to the critical body organ: (a)

The equation for maximum permissible body burden, q , based on a maximum permissible dose rate, R rem/week, is

$$q = \frac{100 \text{ mR}}{3.7 \times 10^4 \times 1.6 \times 10^{-6} \times 6.05 \times 10^5 f_2 \epsilon}$$

$$q = \frac{2.8 \times 10^{-3} \text{ mR}}{f_2 \epsilon}$$

and when $R = 0.3$ rem/week

$$q = \frac{8.4 \times 10^{-4} \text{ m}}{f_2 \epsilon}$$

where 3.700×10^4 = dis/sec per μC ;
 1.6×10^{-6} = ergs/MeV;
 6.05×10^5 = sec/week;
 100 = ergs/g per rad;
 m = mass of the organ of reference (g);
 and ϵ is defined [as in note 1 above].

To derive concentrations in air and water for critical organs other than the gastrointestinal tract the following relationships were used. It was assumed that radioactive material is taken up by the critical body organ at the rate of P $\mu\text{Ci/day}$ and that the biological elimination follows a simple exponential law. Thus:

$$\frac{d(q f_2)}{dt} + \lambda(q f_2) = P$$

The solution with $q f_2 = 0$ when $t = 0$ is $q f_2 = P(1 - e^{-\lambda t})/\lambda$

in which $q f_2$ = burden of the radionuclide in the critical body organ (μC);
 f_2 = fraction of radionuclide in critical organ of that in total body;
 λ = effective decay constant = $0.693/T$;
 T = effective half-life $(T_r T_b)/(T_r + T_b)$ (days);
 T_r = radioactive half-life (days);
 T_b = biological half-life (days);
 t = period of exposure; for occupational exposure $t = 50$ years (in the early publications of NCRP and ICRP t was set to equal 70 years);

P = rate of uptake of the radionuclide by the critical body organ ($\mu\text{C/day}$) = $(M)S$, where M is the concentration ($\mu\text{C/cm}^3$) of the radionuclide in water or in air taken into the body, and S is the product of the average rate of intake (cm^3/day) of water or of air and the fraction of the microcuries arriving in the critical body organ. For occupational exposure at the maximum permissible concentration (MPC) of the radionuclide in water, $M = (\text{MPC})_w$ and in air, $M = (\text{MPC})_a$. In a 24 hr day, the standard man . . . consumes 2200 cm^3 of water and breathes $2 \times 10^7 \text{ cm}^3$ of air. Because of his greater activity during an 8 hr work day, it is assumed that half of this body intake occurs during the work period, viz. 1100 cm^3 of water and 10^7 cm^3 of air. The work schedule for the standard man is 8 hr/day, 5 days/week and 50 weeks/year. Therefore for the average occupational exposure, $S = 1100 \times 5/7 \times 50/52 f_w = 750 f_w \text{ cm}^3$ of water per day and $S = 10^7 \times 5/7 \times 50/52 f_a = 6.9 \times 10^4 f_a \text{ cm}^3$ of air per day.

(a) In the 1979 ICRP formulations, much of this terminology was changed, and the concept of maximum permissible body burden was abandoned. Yet, the principles have not changed drastically.

Note 4

Summary of Alkaline Earth Model, Condensed from ICRP Publication 20 (ICRP 1973)^(b)

Retention in bone volume is described by two functions, one for compact bone and one for cancellous bone. They are respectively:

$$R_{\text{COMPVOLUME}} = p\beta\epsilon^b(t + \theta)^{-b} e^{-r\lambda t}$$

$$R_{\text{CANVOLUME}} = p(1 - \beta)\epsilon^b(t + \theta)^{-b} e^{-\sigma r\lambda t}$$

Theta (θ) is a time-dependent factor which is defined in terms of the whole-body retention function, R:

$$\theta = [f_C 0.8 c\lambda\omega(1 - R)/p\epsilon^b\beta\eta k]^{-1/b}$$

$$R = (1 - p)e^{-mt} + p\epsilon^b(t + \epsilon)^{-b}[\beta e^{-r\lambda t} + (1 - \beta)e^{-\sigma r\lambda t}]$$

(a) A complete bibliography can be supplied to interested readers.

(b) Printed also in *Health Phys.* 24:125-221, 1972.

Total bone surface retention is defined as the solution to the following differential equation:

$$dR_{\text{SURFACE}}/dt = \lambda_{\text{SUR}} (C_{\text{SURFACE}} S - R_{\text{SURFACE}})$$

where S is the fraction of injected activity per gram calcium in the blood plasma; S is related to the whole-body retention function by $S = (-1/\eta k)(dR/dt)$. Retention on cancellous bone surfaces = $\frac{1}{2} R_{\text{SURFACE}}$ and retention on compact bone surfaces = $\frac{1}{2} R_{\text{SURFACE}}$.

The retention functions exclude the effect of radioactive decay and assume that a single intravenous injection has been made. The parameters take on different values for Ca, Sr, Ba and Ra, which are given in Table 27 of ICRP Publication 20.

Parameters not defined above are:

- b = power function slope
- β = fraction of bone volume activity deposited in compact bone
- C = whole-body or total bone calcium
- C_{SURFACE} = calcium content of bone surface pool
- ϵ = time at which the extrapolated whole-body retention is equal to p . (Sometimes called power function time shift.) Is related to turnover time of the initial pool.
- η = excretory discrimination factor for given alkaline earth relative to calcium
- f_C = ratio of total activity deposited in compact bone volume to that in new compact bone
- k = rate of endogenous calcium excretion (urine + feces)
- λ = apposition-resorption rate of compact bone
- λ_{SUR} = rate constant of bone surface pool
- ϕ = fraction of whole-body retention function, R , not in the early exponential term
- r = recycling correction

Translated to a whole-body retention function, the following expression applies:

$$R = (1-p)e^{-mt} + pe^{b(t+\epsilon)-b[\beta e^{-r\lambda t} + (1-\beta)e^{-\sigma r\lambda t}]}$$

where R = the fraction of the injected activity remaining in the body following a single intravenous injection (not including radioactive decay),

ϵ = a small time (0.3–3 days), related to the turnover of an initial pool,

b = power function slope (0.1–0.5), related to diffusion of activity from bone to blood and excretion of part of that activity from the body,

λ = the rate of apposition and resorption in compact bone (2.5%/year),

σ = the ratio of the turnover rates of cancellous and compact bone, (4),

β = the fraction of bone volume activity deposited in compact bone (~ 0.5),

r = a factor which corrects for redeposition of activity in new bone at sites of resorption long after injection (0.83–0.99),

m = the rate constant of a small early exponential in R (0.1–0.8 day⁻¹),

p = the fraction of R not in the early exponential (0.6–0.8),

t = time (from 0 to any time after injection).

This is a six-parameter model of bodily retention because β and r follow from the other parameter values. The time derivative and integral of R are used together with additional parameters to generate consistent internal retention functions for bone surface, new and old compact and cancellous bone, blood, and soft tissue. The bone functions explicitly separate loss of activity by diffusion (diminution) from that by resorption. All the retention functions are assumed to be age-invariant, so that time integrals may be used to simulate the results of any schedule of radioactive intake into the blood, whether from injection, lung, or diet.

Note 5

Contents of volume from the Conference on Occupational Health Experience with Uranium—Chairman, M. E. Wrenn, Arlington, Virginia, April 28-30, 1975 (ERDA 1975)

OPENING SESSION

INTRODUCTORY REMARKS, McDonald E. Wrenn	1
WELCOMING STATEMENT, James L. Liverman	3

SESSION I: REVIEW OF URANIUM IN THE NUCLEAR FUEL CYCLE

Session Chairman: James Sterner

EARLY OCCUPATIONAL EXPOSURE EXPERIENCE WITH URANIUM PROCESSING, Merril Eisenbud	8
ORIGIN AND BASIS OF PRESENT STANDARDS FOR URANIUM, John B. Hursh	25
ISOTOPIC COMPOSITION AND RADIOLOGICAL PROPERTIES OF URANIUM IN SELECTED FUEL CYCLES, Rodney M. Fleischman, R. C. Liikala	35

SESSION II: REVIEW OF THE METABOLISM AND EFFECTS OF URANIUM IN ANIMALS

Session Chairman: J. Newell Stannard

METABOLISM AND EFFECTS OF URANIUM IN ANIMALS, Patricia W. Durbin, M. E. Wrenn	67
INHALATION OF ORES, Bruce O. Stuart	130

SESSION III: OCCUPATIONAL EXPERIENCE AT URANIUM PROCESSING FACILITIES

Session Chairman: Robert E. Alexander

OCCUPATIONAL HEALTH EXPERIENCE WITH URANIUM IN ORE PROCESSING MILLS, Ralph M. Wilde	141
OCCUPATIONAL HEALTH EXPERIENCE WITH A CONTRACTOR URANIUM REFINERY, Richard C. Heatherton	147
HEALTH EXPERIENCE IN INDUSTRIAL URANIUM REFINING OPERATIONS, Gerald J. Sinke, C. Grosclaude	160
OCCUPATIONAL HEALTH ASPECTS OF A FLUORIDE VOLATILITY PROCESS, E. James Freeman	167
URANIUM HANDLING AT THE OAK RIDGE GASEOUS DIFFUSION PLANT, Jack C. Bailey	185
INDUSTRIAL FUEL FABRICATION OPERATION, Charles F. Sanders, R. D. Bibb	195

SESSION IV: HEALTH EFFECTS

Session Chairman: William W. Burr, Jr.

NUCLEAR REGULATORY COMMISSION OCCUPATIONAL EXPOSURE EXPERIENCE AT URANIUM PLANTS, Jack R. Metzger	205
A STATISTICAL SUMMARY OF ERDA CONTRACTORS' ENRICHED URANIUM EXPOSURE EXPERIENCE 1957 - 1974, Donald M. Ross, C. M. Campbell	215
A REVIEW OF URANIUM EXCRETION AND CLINICAL URINALYSIS DATA IN ACCIDENTAL EXPOSURE CASES, Michael W. Boback	225
CANCER MORTALITY AMONG URANIUM MILL WORKERS, Victor Archer, J. K. Wagoner, F. E. Lundin	244
A REVIEW OF THE BELL STUDY, Sidney Marks	256

SESSION V: EXPOSURE STATUS OF URANIUM WORKERS

Session Chairman: Charles M. West

URANIUM IN VIVO SPECTROMETRY, L. Max Scott, C. M. West	263
URANIUM IN MAN BASED ON URINARY EXCRETION DATA, Kenneth R. Heid, W. P. Walsh, J. R. Houston	297
URANIUM IN THE TISSUE OF OCCUPATIONALLY EXPOSED WORKERS, Evan E. Campbell, J. F. McInroy, H. F. Schulte	323
PANEL DISCUSSION, Asher J. Finkel, Thomas A. Lincoln, Authors of Session IV and V papers	351

SESSION VI: ASSESSMENT OF THE OCCUPATIONAL ENVIRONMENT

Session Chairman: Donald M. Ross

ANALYSIS OF LONG TERM DATA ON URANIUM IN AIR AT Y-12, Merwyn Sanders	364
OCCUPATIONAL RADIATION EXPOSURE EXPERIENCE PADUCAH GASEOUS DIFFUSION PLANT, Richard C. Baker	387
THE ROLE OF PARTICLE-SIZE IN THE EVALUATION OF URANIUM HAZARDS, Thomas T. Mercer	401
CONSIDERATIONS IN DEVELOPING A WORK-PLACE STANDARD FOR SAMPLING AIRBORNE URANIUM, Lysle C. Schwendiman, B.V. Andersen, J.M. Selby, D.A. Waite	419
PURPOSES AND FUNCTIONS OF AIR SAMPLING PROGRAMS, Harry F. Schulte	436

SESSION VII: SUMMARY

SUMMARY PANEL DISCUSSION, James Sterner, J. Newell Stannard, Robert E. Alexander, William W. Burr, Jr., Charles M. West, Donald M. Ross	443

Preface to Section V Instrumentation

Instrumentation and methodology are sometimes described in the chapters already written and to follow, but only when they were key factors to the development under discussion.

Obviously, tremendous advances have been made in both since the days when some of the most basic measurements were made with relatively crude instruments. Progress in methodology is too specifically tied to the individual subjects under investigation to be reviewed as an entity. Those needing most to be described appear in connection with the research reviewed. However, integral to every experiment was the means to measure radioactivity in its various forms, and this needs an integrated discussion. The progression from simple electrometers to computerized and automated counting systems affected all aspects of the research reviewed in this book. Brief chronologies of the major steps in this progression are contained in the two chapters in this section.

Two major types of instrumentation can be identified. The first type applies primarily to the detection and measurement of radioactivity from radionuclides for purposes of monitoring plant operations or in the field. Many of the developments most identified with nuclear energy facilities of all kinds, including the many environmental measurements, were in this category. These instruments were, by and large, intended to be portable, rugged, easily operated, and versatile. Most of them met these criteria, although some of the sophisticated in-plant monitoring devices outgrew any reasonable definition of portability. Later developments in electronics and radiation detectors permitted a sharp reduction in size and weight of the truly field-type instruments.

The period of most rapid growth of these instruments occurred under the auspices of the Manhattan Engineer District (MED) during World War II. For security reasons, in part, and in part to add some color to what was sometimes a grim set of working conditions, many of these field and monitoring instruments were given code names that related either to what they did or what they looked like, but not to what their real purposes were. They were a governmental monopoly until the end of the war, when several private groups began manufacturing and improving these devices. It is no coincidence that these private groups were headed by individuals who had had much to do with the MED developments.

The second major type of instrumentation pertinent to the researches described in this book was used primarily in the laboratory. These were sensitive,

precise, and, especially in the middle years, heavy and bulky. An exception to the latter were the early electrometers and simple electroscopes and the photographic methods. Actually, sensitivity and precision were sufficient even with the early instruments to allow, for example, working out of the natural series of radionuclides (described in the preface to the first section of this book), as well as classic research. However, the devices available were difficult to set up and operate, and data accumulation was a slow process. The vacuum-tube amplifier changed all that, but the early instruments required much space, required considerable power, and had personalities of their own. A laboratory without a resident electronics expert was in deep trouble. Only with the development of solid-state circuitry and miniaturization has the laboratory instrument for measuring the radioactivity from radionuclides become reasonably compact and trouble free.

Precision designs of laboratory instruments began in 1928 in order to fulfill the requirements of the recently defined roentgen unit. In this area, the U.S. National Bureau of Standards was a leader in the development of the standard air ionization chamber as well as a center for calibration of field instruments. Laboratory instruments were under development throughout the 1930s for measurements of radioisotopes produced by accelerators. They underwent further development during the years of World War II, but not under the same conditions as the field and monitoring instruments. As the uses of radioactive tracers became commonplace, private instrument manufacturers supplied the needs of a great variety of laboratories, especially those for chemistry, biology, and medicine. To a degree, all of these, both specialized and routine, owed much of their development to the needs of and support from the Atomic Energy Commission.

In the decade of the seventies, and even more clearly in the decade of the eighties, the major developments in laboratory instrumentation have their roots in various aspects of nuclear medicine (chapter 20).

One important distinction between the two types of purpose and procedures is the degree of needed preparation of the sample. For the field and monitoring operations, measurements had to be made with the radionuclides in whatever form they existed. For the laboratory procedures, there were sometimes elaborate preparative steps, for example, to get a weak beta emitter or an alpha-particle emitter free from matrices such as body tissue, excreta, chemical compounds, etc., and thus reduce the interference with measurement that would otherwise occur. Frequently, these preparative steps took up more time and space than the radiation measuring steps. Typical examples are seen in chapter 12, figures 12.25 and 12.26, where the "mile of track" needed for preparing milk or separating noble gases for measurement is pictured. Another example, one for separating ^{14}C from biological compounds before measurement as CO_2 gas, is shown in figure PI-1.

Such preparative steps have become simpler with the development of liquid scintillation counting and other modern advances, but these came into general use relatively late in the decades covered by this book.

The field of instrumentation is special, and its history needs description by individuals who were closer to the developmental phases than was this author. Therefore, he enlisted help which was generously supplied by his former colleague and long-time friend, Dr. Howard L. Andrews (PHS, retired), formerly at the National Institutes of Health, Bethesda, Maryland, and later the University of Rochester, now residing in Jamestown, Rhode Island; and by another long-time

FIGURE PI-1. The "mile of track" needed to prepare biological materials for measurements of carbon-14 as $^{14}\text{CO}_2$ gas. In the background is Dr. Leon L. Miller, one of the developers of the method at the University of Rochester. (Photo courtesy of Dr. Irving Spar.)

friend and aficionado of the history of science, Ronald Kathren, now at Richland, Washington. Mr. Kathren has had broad experience in industry and contractor laboratories and has gathered an enviable collection of old to ancient radiation measuring instruments and literature concerning others, while Dr. Andrews has outfitted and managed several laboratories and field operations. I am greatly indebted to these two men.

Chapter 17, by Dr. Andrews, traces the development of instruments intended primarily for laboratory use. Chapter 18, by Mr. Kathren, considers the development of instruments for monitoring and field measurement of the radiations from radionuclides. Both emphasize developments in the United States because of the scope of the book, but no different principles are involved for instruments developed in any part of the world. Neither chapter dwells much on the preparative steps involved before measurement. The reader can find them well-documented in the original literature, which is copiously referenced in the pertinent chapters.

It should be clear from these chapters that development of instrumentation was continuous and significant throughout the years we are reviewing. The changes in recent years have added to convenience and speed more than to precision and sensitivity. Again, we must express admiration for what the early workers did with laborious and temperamental methodologies.

Capsule Chronology^(a)

- 1895–1900** Photographic emulsions and electroscopes are the primary instruments used when radioactivity is discovered and the first radioactive elements isolated.
- 1900–1924** Gradual development of mechanical electrometers.
- 1911** Microscope used to count grain densities in photographic film.
- 1928** Roentgen unit accepted.
Description of basis for Geiger-Müller counter—soon called G-M tube.
- 1929** “Free air” ionization chambers used as primary standards.
Nuclear track photographic plates developed.
- 1930** Special vacuum tubes with high resistance and low current drain developed, e.g., the General Electric type FP-54.
Early count rate meter.
- 1930s** Much work on methods for producing quartz fibers for electrometers.
- 1933** DuBridge and Brown compensating circuit.
- Mid-1930s** Vacuum-tube electrometers gradually replace mechanical electrometers.
Work on quenching gases for G-M tubes.
- 1935** Eastman NTA plate in common use. Soon followed by NTB stripping emulsion.
- 1936–1960s** “Cavity chambers” used as secondary units for measuring ionization in a small volume of gas. Much work on composition of walls of such chambers. Victoreen “R-meter” is an early example.
- 1937** Lauritsen electroscope.
Extrapolation chamber of Failla.
- 1939** Binary scaler introduced as auxiliary pulse-counting equipment.
More useful count rate meter developed.
- 1940** Photomultiplier tube developed.
- 1940s** Enormous strides in ion chambers, vacuum tube electrometers, improved G-M tubes, pulse counting, discriminators, linear amplifiers, autoradiography, etc., taken under MED^(b) auspices.
- 1947** Higinbotham circuit.
Improved linear amplifiers.
Early pulse height analyzer.
Dynamic condenser electrometer (Palevsky, Swank, and Grenchik).

(a) The capsule chronology and summary and commentary were written by J. N. Stannard and were not reviewed by the chapter's author.

(b) For abbreviations and acronyms, see Appendix D.

1948 Halogen quenching gases introduced.

1950s The following were either introduced or improved significantly during the 1950s:

Vibrating reed electrometers.

Proportional counters.

Energy discriminators, pulse height analyzers.

Thallium-activated sodium iodide crystals.

Gamma-ray spectrometers.

Liquid-scintillation techniques.

Semiconductors.

Late 1950s Worldwide search for amber to use as electrical insulator in radiation measuring devices. Replaced later by synthetic plastics.

1960s Large crystals make whole-body counters able to measure many more radionuclides in the human body (Argonne, Los Alamos, and others).

Particle track-etching techniques developed.

1970s Thermoluminescence comes into wide use.

1980s Computer-assisted equipment expands greatly.

Chapter 17

Laboratory Measuring Instruments

by Howard L. Andrews, Scientist Director U.S. Public Health Service (Ret.) and former Professor of Radiation Biology and Biophysics, University of Rochester School of Medicine and Dentistry.

I. The Pioneer Years, 1895 to 1940

A. In the Beginning

Sensitive instruments and measuring techniques were immediately available for application to the pioneering discoveries of Roentgen and Becquerel. The initial detection of x rays late in 1895 and the beta particles from radioactive decay three months later were made with photographic emulsions. Electroscopes using thin gold foils as the sensing element were in use at the time of the original discoveries and quickly demonstrated the ionizing capabilities of the newly discovered radiations.

The use of photographic emulsions has continued and for particular purposes they provide unique information, but techniques based directly on the electrical detection of ionization have borne the main burden of radiation measurements.

Electrometers of many designs soon supplemented the simple electroscopes. The distinction between the two is subtle and need not concern us here. Madame Curie used the "electric method" in her early studies, including those that led to the determination of the activity of a weighed sample of radium, from which the decay constant and the half-life could be calculated.

B. Moving-Element Electrometers

The ions produced in a closed chamber by a single alpha particle could be barely detected by the most sensitive electrometers. These instruments utilized the movement of a thin foil, a fine (about $0.5\text{-}\mu\text{m}$) quartz fiber, or a moving vane suspended by a fine fiber. The position of the moving element was determined by a microscope or with a lamp, mirror, and scale.

Mechanical electrometers are sensitive but temperamental detectors of electric charge or potential, depending upon the circuit arrangement. Ion currents can be measured from the rate of movement of the sensing element or by its

steady deflection when the current flows through a high resistance (10^7 to 10^{10} ohms).

Mechanical electrometers are very difficult to set up and adjust to optimum working conditions. As the sensitivity is increased, the moving element tends to become unstable, eventually responding to internal conditions rather than to external signals. Fluctuations in the Brownian movements of the gas molecules in the instrument case produce a fluctuating zero position. Electrometers are necessarily enclosed in metal to protect against air currents and to provide electrostatic shielding. Massive copper shielding is usually added to reduce thermal gradients, and an elaborate vibration-damping mount is usually required.

At high sensitivities, the response time of an electrometer is very long, although it can be reduced somewhat by a partial evacuation of the case—another complication. A single rate-of-charge measurement may require an hour or more. The results obtained with these instruments are a tribute to the patience and the experimental skills of the early workers.

The designs of Hoffman in 1912 and of Lindemann in 1924 probably represent the ultimate in mechanical electrometers. Although some of these instruments were in use well into the 1940s, they were then being replaced with vacuum-tube electrometers. From then on, they played no role in the rapidly developing field of radiation.

Although it lacked the ultimate sensitivity of some other designs, the Lauritsen electroscope (Lauritsen and Lauritsen 1937) deserves special mention. The sensing element consists of a simple T-shaped quartz fiber about $5\text{ }\mu\text{m}$ in diameter, made conducting with a thin film of gold and mounted directly in an ionization chamber. The position of the fiber is read with a microscope and an eyepiece scale. An electric charge (which could be produced by rubbing a pocket comb on some wool) placed on the system deflects the fiber from its zero position. Ions produced in the chamber neutralize some of the charge and the fiber returns toward its zero position at a rate that depends upon the rate of ionization.

A versatile laboratory instrument, the Lauritsen design was also rugged enough for field use. These electroscopes were used by the Japanese at Hiroshima to give the first indication that ionizing radiation had accompanied the detonation. They were in use as late as the 1950s in some studies in radiobiology but were then being replaced by vacuum-tube electrometers. Pocket dosimeters, widely used today in personnel monitoring, are adaptations of the Lauritsen design.

C. Ionization Chambers

In principle, an ionization chamber consists of an enclosed gas volume with two collecting electrodes, one of which is highly insulated and is connected to an electrometer. In practice, certain special shapes, sizes, and constructions are best suited to specific purposes.

In 1928, the roentgen (r) was accepted by the International Commission on Radiological Units (ICRU) as the unit of radiation dose (Taylor 1958). Based on the number of ions produced in air, the strict fulfillment of the definition requires an instrument in which all of the ions collected do indeed originate in air. These "free-air" chambers (Taylor 1929) are suitable for use only in standardizing laboratories, such as the National Bureau of Standards (NBS), where they have been available for the calibration of secondary standards. Over

limited energy ranges, these secondary standards may closely approximate the response of a true air chamber.

Much theoretical and experimental work has been done over an extended period of time on these secondary or "cavity chambers" (Gray 1936; NBS 1961). In a cavity chamber, the measured ionization is produced in a small gas volume (usually air) enclosed within solid walls. The composition of the walls can be made essentially "air-equivalent" or "tissue-equivalent" as required, and the wall thickness chosen to be compatible with the ranges (energies) of the ions to be collected. One of the earliest instruments of the cavity-chamber type is the r-meter manufactured by the Victoreen Instrument Company. The r-meter is essentially a string electrometer with removable cavity chambers of various volumes and wall thicknesses. The original Victoreen design was based on the earlier work of Fricke and Glasser (1925) and on that of Glasser, Portmann, and Seitz (1928). With only minor modifications, the r-meter is in extensive use today.

The "extrapolation chamber" developed by Failla (1937) was designed to permit dose determinations in a tissue having a uniform concentration of a radioisotope. It also serves to measure the dose due to a beta emitter located at or just below the surface of the skin. The extrapolation chamber consists of a parallel-plate ion chamber with an adjustable ion-collecting space between the electrodes. A series of measurements taken at various collecting volumes can be extrapolated to zero volume to give the dose independent of the disturbing effect of the chamber itself.

D. Materials of Construction

Specially selected materials were required for the construction of ionization chambers and electrometers, and this holds true for the more sophisticated instruments in use today. Improvements in instrument performance have come more from design refinements and the use of new and improved components than from the use of new fundamental principles upon which the measurements are based.

From the time of the earliest electroscope to the present, electrical insulators have been particularly critical components. Natural amber and crystalline quartz were quickly recognized as superior insulators. Cast rhombic sulphur was found to be suitable for some less critical applications and was much cheaper. Amber was particularly useful because it can be machined easily into useful shapes. In the late 1950s, a worldwide search was undertaken to procure as much of this critical material as possible. Later, the development of synthetic plastics relieved the pressure on scarce amber and quartz, and eventually insulators with superior qualities were produced. In particular, some synthetic materials show a greater stability at high radiation doses and less "soak-in," a process where charges migrate in and out of the insulator.

For many years, the multimegohm resistors were made by drawing lines with a graphite pencil or with drawing ink on a cardboard or celluloid backing. The resistance values obtained were largely a matter of chance and were subject to undesirable changes with temperature and humidity. During the 1940s, stable ceramic resistors were developed by the S. S. White Dental Manufacturing Company, and soon other companies were offering comparable items.

Prior to the enormous instrument requirements of the Manhattan Engineer District (MED), much of the early equipment was made by the users. *Procedures in Experimental Physics* (Strong 1947), a classic text first published in 1938,

devoted one chapter to methods of producing the fine quartz fibers needed for electrometers. Another chapter described methods for depositing electrically conducting films on the fibers. Still another chapter gave detailed instructions for the manufacture of Geiger-Müller (G-M) tubes.

One of the lost spectacles of the early physics laboratories is the production of quartz electrometer fibers by the cross-bow method. A bow and arrow were set up at the end of a long corridor with the arrow restrained by a short piece of quartz rod. When the quartz was suddenly melted with an oxy-hydrogen flame, the released arrow generated a fine fiber, which was to be found by a hands-and-knees search on the floor, previously covered with black cloths.

As laboratory measurements became more reliable and sensitive, it became evident that low levels of naturally occurring radioactive isotopes are present in many materials. Unless all structural components are carefully chosen, the instrument itself may contribute more activity than the sample being assayed. One of the first applications of the vacuum-tube electrometer was to a detailed investigation of materials of interest in instrument construction (Bearden 1933).

E. Radiation Sources and Applications

Before the release of classified information from the MED, there were relatively few sources of radiation and few applications. Instrumentation was correspondingly limited. Patients were being treated with "soft" x rays (30 to 100 kVp) for superficial lesions, and "deep therapy" at 250 kVp was used for deep-lying tumors. Engineering developments were slowly pushing the "hard" x-ray voltages upward to 2 MeV during the 1930s and 1940s.

Some organ tumors were treated by implanting radon "seeds" utilizing radon gas pumped off from a solution of ^{226}Ra . A large hospital with an active cancer service might have a radon plant consisting of a 100- to 1,000-mCi solution of radium bromide. The plant operator used a hand-operated mercury pump to force the gas liberated by radium decay into fine glass or gold capillary tubing. This tubing was then sealed off into a series of seeds, each calculated to have the activity specified by the radiologist for the case in hand.

After sealing, each seed was checked by comparing its activity to that of a standard source. The usual arrangement consisted of an ion chamber-electrometer setup with carefully controlled source and chamber positions. The NBS developed some standards to which the seeds could be compared. Curtiss et al. (1940) reported on plans of the Bureau to provide radium samples containing either 10^{-9} or 10^{-11} grams of ^{226}Ra in 100 ml of solution, sealed ampoules of thorium, and standard samples of radioactive rock.

Industrial applications of radioactive materials were limited largely to their use in self-luminous paints. Many of these preparations were crude mixtures of a variety of naturally occurring radioisotopes. Few activity measurements were made, and in many cases the composition of the mixture was unknown. These uncertainties introduced serious difficulties when attempts were made to deduce allowable exposure limits from the injuries observed in the New Jersey dial painters.

F. Manmade Radioisotopes^(a)

The early 1930s were years of great scientific productivity. Chadwick reported the identification of the neutron in 1930. Joliot and Curie produced artificially

(a) [See also chapter 5.]

induced radioactivity in 1934 utilizing the alpha particles from naturally occurring isotopes. The era of high-energy particle accelerators opened when Lawrence and Livingston (1932) described the design and performance of the first magnetic resonance machine, named the cyclotron. This was quickly followed by the development of the electrostatic accelerator (Van de Graaff, Compton, and Van Atta 1933). No longer was man restricted to the naturally occurring radioisotopes; he could now make his own. Uses now expanded rapidly, and this stimulated the development of equipment for the quick and accurate assay of a rapidly increasing number of isotopes.

In spite of the increased production and use, there were some uncertainties as to just what was being measured. During 1938 and 1939, a series of papers in *Physical Review* discussed the possibility that the beta particles emitted by radioactive nuclei had a variety of masses instead of being strictly identified with the negative electron. Some thought that energy considerations required slow-speed betas to have a greater rest mass than those of higher energy (Jauncey 1938). The theoretical studies of Pauli and the acceptance of the existence of the neutrino settled the controversy in favor of a single beta particle rest mass.

G. Vacuum-Tube Electrometers

Vacuum tubes, applied enthusiastically to the field of communications, seemed to offer important advantages over mechanical electrometers. During the 1920s, astronomers had been attempting to use vacuum tubes as electrometers to measure the minute electric currents produced in photoelectric cells coupled to their telescopes. The problems that they encountered were similar to those involved in ion-current measurements. Only partial success was achieved with the types of tubes that were being used successfully in communications, where performance demands were less severe.

Eventually, special attention was given to the critical parameters in tube design, and some tubes with remarkable characteristics were developed. Elaborate steps were taken to obtain the highest possible vacuum, and, to eliminate ionization in any residual gas, the tubes were operated at only 4 to 6 V, well below any ionization potentials. Internal mounts and external leads were designed to have the greatest possible resistance to leakage currents. Victoreen, Western Electric, Westinghouse, and General Electric each produced electrometer tubes, with the General Electric type FP-54 the most outstanding (Metcalf and Thompson 1930). Ion currents of 10^{-17} A or even less could now be measured routinely and rapidly.

Compensating circuits (DuBridge and Brown 1933) were developed to minimize disturbances due to changes in battery voltages and to fluctuations in filament emission. Ion current measurements could now be obtained from a rugged galvanometer or microammeter in the plate circuit of the electrometer tube. The hypercritical high-resistance, low-leakage circuit was now limited to the ion chamber itself and to the grid of the electrometer tube.

Although the vacuum tube brought its own particular problems, the critical mounting and shielding required with the mechanical electrometers was eliminated. The time required to make a measurement was sharply reduced. During the exploratory phase of any technique, one is gratified for any measurement, however much effort is required to make it. In moving into exploitation, speed and ease of measurement become important. The introduction of the vacuum tube into ionization measurements not only shortened assay times but also

permitted measurements by personnel who would have had great difficulties with the mechanical electrometers.

H. Pulse Counters

When the ion-collecting voltage across an ion chamber is increased, primary ions generated by the radiation may acquire enough energy to produce secondaries by collision. These secondaries add to the primaries to produce a pulse of ionization 10^2 to 10^9 times as large as that from the primaries alone, the amount of amplification increasing with increasing voltage. An assay now consists of counting the number of pulses rather than measuring the total primary ionization produced by some initiating event.

By 1908, Rutherford and Geiger were making use of secondary, or avalanche ionization, using the Geiger point counter to detect alpha particles. Later, the needle point was replaced by a fine wire (about 0.1-mm diameter) stretched along the axis of a cylindrical cathode (Geiger and Müller 1928). These devices were the ancestors of the modern proportional and G-M counter tubes.

At atmospheric pressure, useful values of amplification require stable sources of 1,000 to 5,000 V, values not readily attainable with the early (or modern) batteries. Full exploitation of gas amplification awaited the development of highly stabilized sources of high voltage made possible with vacuum tubes.

At gas amplification factors of 10^2 to 10^3 , the size of the avalanche pulse is strictly proportional to the number of primary ions formed by the radiation. These pulses may still be too small for direct recording, but vacuum-tube linear amplifiers were designed to raise the signal level while still maintaining proportionality. Because of the overall proportionality of the system, such a counter can readily discriminate between the massive localized ionization of an alpha particle and the sparse ionization of a beta.

When the gas pressure in a pulse-counter tube is reduced to perhaps 10 cm of mercury, gas amplification factors of 10^7 to 10^8 may be obtained with voltages of less than 1,000. The ultimate sensitivity has been attained because a single ion pair is now capable of initiating an ion pulse up to the full capability of the tube. A massive primary ionization can do no more, and the tube has lost its ability to discriminate between different sizes of primary events.

I. Making G-M Tubes

In the decade following the Geiger-Müller paper of 1928, a spate of papers appeared on various aspects of G-M tube manufacture. An intense interest in pulse counting was generated by the controversy over the nature and origin of cosmic rays, in which Nobel laureates Compton and Millikan were the chief antagonists.

The basic principles involved in pulse counting were only gradually discovered during this period, and many of the early papers were in the nature of cookbook recipes. Some tubes were fast, with pulses of 10^{-5} -sec duration; others were slow, with 0.1-sec pulses, and there were many failures.

One of the earliest problems involved the tendency of the G-M tube to respond to a single ionizing event with a series of repetitive pulses. This tendency toward continuous discharge could be suppressed by adding a high resistance, but the response time of the tube then became very long. A variety of vacuum tube circuits (Neher and Pickering 1938) were devised to stop, or quench the discharge and ready the tube for another without lengthening the response time.

A wide variety of counting gases were studied, leading to the choice of argon for most applications, a choice still valid today. Many gas mixtures were tried, and Trost (1937) reported that the addition of some 10% of certain complex molecules to the basic counting gas would suppress the tendency to go into continuous discharge. This finding was vigorously pursued, and quickly self-quenching tubes containing some organic molecule such as ethanol or xylene were in common use. Some of the organic quenching gas is used up in each discharge so these tubes have a finite counting life, and, in addition, their efficiency is somewhat temperature dependent. In spite of these drawbacks, the old non-self-quenching tubes were quickly outmoded for most applications.

As the G-M tube became more reliable, it was applied to a variety of assays of interest in biology and radiochemistry. On the one hand, thin "windows" were developed to improve the entrance of low-energy beta particles into the sensitive volume. On the other hand, some tubes were made with unusually heavy cathodes to enhance the absorption of gamma-ray photons, which were then detected through the liberated electrons.

One of the unusual applications was the use of G-M tubes (Evans 1937) to measure the radium content in living persons, the first human whole-body counter.

J. Auxiliary Pulse Counting Equipment

The avalanche discharge in a G-M tube is sufficient to produce a detectable deflection in a string electrometer, but the response time of the string is very long compared to the pulse duration, and so the full counting capability of the tube cannot be realized. High-speed pulse counting followed the introduction of scaling circuits. These devices were typically based on a binary or scale-of-two vacuum-tube circuit, which passed along one pulse for every two incident upon it. A series of these circuits reduces the number of input pulses by factors of 2, 4, 8 . . . 2^n . Many variants of the basic binary scaler were introduced during the 1930s (Lifschutz 1939).

With a sufficiently high scaling factor, the number of output pulses can be recorded on a mechanical counter. In the 1930 era, the choices in these counters was limited, and none had been designed to be driven efficiently by a vacuum tube. Central Scientific Company offered a slow register that required a large amount of power. A limited number of message registers were available from Western Electric, and later Cyclotron Specialties designed a counter more suited to vacuum-tube operation. None of these mechanical devices was entirely satisfactory.

With a scaling circuit, the total pulse count over some determined time required multiplying the reading of the mechanical register by the scaling factor, and then adding the number of pulses that were in the scaling system but which had not yet activated the register. Symbolically:

$$\text{Pulse count} = \text{Register} \times \text{Scaling factor} + \text{Interpolation}$$

The chance for an error in making this calculation for every assay is substantial, in spite of help from various devices designed to facilitate the process.

K. Count-Rate Meters

When a count rate of one hundred or more a minute is available, the pulses can be electronically averaged over some convenient time interval and the average

displayed on a deflection-type meter. Rate meters are particularly useful for studying the decay of radioisotopes because the meter can be connected to a chart recorder to provide a continuous record of the activity. One of the earliest rate meters was described by F. V. Hunt in 1930. Various design improvements followed, and by the end of the decade, sophisticated rate meters incorporating many of the features in use today were available (Evans and Alder 1939). The rate meter is one example of an instrument whose development came from the demands of biology and chemistry rather than from cosmic-ray research.

L. Photographic Emulsions

The first evidence for the existence of ionizing radiations came from the general blackening of photographic emulsions and from the shadows cast on them by strong absorbers of the radiations. It was quickly discovered that each of the three types of radiation (alpha, beta, and gamma) could produce an effect on photographic materials. However, electric methods of ionization measurements became preferred for accurate quantitation. In 1935, Compton and Allison would state, "Though it is usually employed to give only qualitative results, the photographic plate can also be adapted to precise quantitative comparisons of x-ray intensities." (Compton and Allison 1935)

Film blackening was quickly exploited by physicians for the x-ray examination of deep-lying body structures. This application required fine-grained emulsions of high sensitivity to photons. The market demands were large, and improvements by film manufacturers led to finer detail in the shadow pictures with a reduced radiation exposure of the patient.

Some attempts were made to use films for measuring the exposure of radiation workers, but most of these were of dubious value because of the lack of controlled conditions of exposure, processing, and evaluation. In one laboratory, a worker's exposure was considered acceptable if a newspaper could be read through a film of unspecified sensitivity, processed in casual, uncontrolled fashion.

Discrete tracks produced by individual alpha particles were observed very early, and, by 1911 microscopic examination of the developed emulsions were being made to determine grain densities along the tracks.

The chief push for better particle track counting came from the physical rather than from the biological sciences. Cosmic-ray investigators required unusually thick emulsions in order to record reasonable portions of the tracks of high-energy particles. Ilford, Agfa, and Eastman each were producing special nuclear track plates by the late 1920s. By 1935, the Eastman NTA plate was in common use, and the NTB stripping emulsion quickly followed. The emphasis was still on physical applications. A comprehensive review (Shapiro 1941) made no mention of uses of nuclear track plates in biology, although there had been some limited applications many years before (Lacassagne and Lattès 1924).

II. From Eclipse to Declassification

A. Transition

A few pioneering biological tracer studies had been done in the 1930s, utilizing ^{210}Pb obtained from used radon seeds whose gamma-ray activity had dropped below useful therapeutic levels. Many other elements were of greater biological interest, and these only awaited availability to be rapidly exploited. With the

discovery of artificial radioactivity and the construction of high-energy particle accelerators, many new radioisotopes became available in useful quantities.^(a)

The late 1930s saw sharply increased interest in radiation and the use of radioactive isotopes. There was a corresponding increase in the number of papers published on the related instrumentation. Then the decision was taken to proceed with research on the possibility of producing nuclear weapons. The MED was created, and General Leslie Groves was appointed director in mid-1942, to remain until December 31, 1946.

The magnitude of the task ahead was appreciated early, and a large number of those who had been working with radiation were recruited into the project. Physical scientists were needed to develop methods for producing the parent materials and for fashioning them into an energy-releasing structure. Biological scientists were needed to investigate pharmacological properties of a host of new, manmade elements and of others previously known only as laboratory curiosities.^(b) All scientific results originating within the project were classified and barred from free publication.

The number of papers published on all phases of radiation research dropped sharply. Previously, most of the papers on instruments and techniques had been published in *Review of Scientific Instruments*. A cursory survey of the record of this journal shows the effect of the MED recruitment:

Number of Papers in *Review of Scientific Instruments* Related to Radiation Measurements

1940 — 15	1946 — 18
1941 — 12	1947 — 37
1942 — 6	1948 — 50
1943 — 7	1949 — 42
1944 — 1	1950 — 34
1945 — 3	

These data should have been of more than passing interest to our opponents in World War II.

B. The Organization

Faced with an enormous and perhaps impossible task, the MED decided to push concurrently several promising lines of research. A series of laboratories was set up at Berkeley, Chicago, Los Alamos, Oak Ridge, and Rochester, to name only a few. Each laboratory had a specific task, such as production, purification, weapons design, or biological effects. Each had specific instrument requirements, although there were areas of overlap and some common problems. Each had an instrument group in partial, but frequently incomplete, communication with the others.

(a) [See also chapter 5.]

(b) [Details in chapters 6 and 7.]

At the start of the project, each group had available the instrument types described in section I of this chapter. In addition, each had some relatively primitive instruments for neutron measurements. Discussion of these instruments has been omitted here, because only under the most unusual conditions will neutrons arise from emitters internal to the body.

C. The Instrumentation Task

Formidable problems faced the instrumentation groups. The fission process would produce large numbers of hitherto unknown isotopes whose individual radiations had to be determined. Separation and purification procedures would require instruments to properly identify and quantitate the individual components. Alpha-particle assays, frequently in the presence of high beta activity, would become of paramount importance in the production of fissionable materials and in studies of their biological fates. Before the creation of the MED, radioactive materials had been relatively scarce, and instrument developments had emphasized the assays of small, submicrocurie quantities. These assays would still be needed, but, in addition, multimicrocurie activities were expected, and instruments had to be devised to cope with them.

Developments proceeded on all types of instruments. Ion chambers and vacuum-tube electrometers were needed in many applications. The production of improved G-M tubes was expanded, and new designs of auxiliary pulse counting equipment were made. Upper and lower energy discriminators were added to linear amplifiers to permit the counting of only a limited energy range, an aid in identification and in the reduction of background counts. Photographic techniques (autoradiography), using either special nuclear-track or conventional emulsions, were developed to study the distributions in tissues of the many newly available radioisotopes (Axelrod and Hamilton 1948).

Radiation safety formed an important part of the MED program, and again new instruments and techniques were needed. Assay methods for all kinds of emitters had to be devised, utilizing air and breath samples, urine and fecal specimens, and surface wipes. In most cases, the assays required both identification and quantitation.

Throughout the program, some very grave value judgments had to be made. Instrument improvements tend to become a continuous process as new materials, components, and ideas are fed into the research and development system. Under great time pressure, when must development be frozen and manufacture start, perhaps to produce an instrument that is partly obsolete by the time it is in use? It is a tribute to all concerned in the MED that the instruments and techniques that were developed, while perhaps not always ideal, were adequate for the job at hand.

D. Declassification

At the conclusion of World War II, the decision was taken to publish all of the findings of the MED that did not jeopardize national security. Declassification proceeded rapidly, considering the enormity of the task and the irreversible nature of the releases.

Much of the declassified material was published by McGraw-Hill in the National Nuclear Energy Series. The project activities were divided into eight divisions:

- I. Electromagnetic Separation Project
- II. Gaseous Diffusion Project
- III. Special Separation Project
- IV. Plutonium Project
- V. Los Alamos Project
- VI. University of Rochester Project
- VII. Materials Procurement Project
- VIII. Manhattan Project

Division V, Volume 2, *Ionization Chambers and Counters*, written by B. B. Rossi and H. H. Staub (1949) is of the most present interest. One of the authors' aims was to show "how we did it," and to some extent the volume today has something of a cookbook flavor—not so when it was published. It was evident that the MED had added enormously to the basic knowledge behind the practical design of radiation measuring instruments.

Individual scientific papers were also published on many parts of the instrument program. Only a few can be mentioned here. Higinbotham, Gallager, and Sands (1947) published the detailed design of a binary scaler that was to be a standard of performance for several years. Similarly, Jordan and Bell (1947) developed a vastly improved linear amplifier for use in proportional counting. The alpha-proportional counter of Simpson (1947) provided efficient counting of alpha particles with a high rejection rate for betas.

In spite of the remarkable progress made during the project, instrument development was by no means complete, and this situation will continue as long as radiation measurements are made. However, postproject developments started from a much higher quantum level than existed initially.

III. After the MED

A. The Takeoff

The use of radiation and radioactive materials expanded explosively following the declassification of MED information. High-voltage accelerators of several kinds were designed and built. Some of these produced very penetrating x-ray beams used in the treatment of deep-lying tumors and in commercial applications. Others produced radioisotopes for a proliferating demand.

Both the number of isotopes and the quantities available increased dramatically in 1948 with the release of products from the reactor at Oak Ridge National Laboratory. Carbon-14 and hydrogen-3 (tritium) were of particular importance in biology and medicine, but their relatively low-energy beta emissions posed some measurement problems.

Radiochemical companies began to take over the sometimes difficult job of incorporating radioactive atoms at specific locations in complex molecules. A large number of labeled compounds became almost stock items, in microcurie quantities for tracer studies and in millicuries for the controlled destruction of unwanted biological tissues. Multicurie sources were used for the inspection of metals for hidden flaws and for a variety of irradiations. In one large medical institution, the amount of radioactivity utilized increased exponentially for over fifteen years, with a doubling time of about three years.

Regulations designed to ensure the radiation safety of workers, patients, and the general public were developed and promulgated. Proofs of personnel competence and adequate facilities were required to obtain materials from the

Atomic Energy Commission, successor to the MED. Building on the safety requirements developed by the MED, instruments were now required for radiation safety measurements as well as for the assays of primary interest. Field samples were brought to the laboratory for analysis, and bioassays of breath, urine, or other biologicals served to determine the body burden of internal emitters. In these measurements, the identification of the emitters was as important as the activity. The Health Physics Society, organized in 1955, continues to foster the development and application of practices that will ensure the safe uses of radiation.

Pressures on instrument manufacturers came from several directions. Reliability was, of course, of paramount importance. Increased response to low activities was demanded in order to reduce assay times and to permit the use of smaller amounts of active materials.

It is axiomatic that only those ionizations that occur within the sensitive volume of the detector will be recorded. Some of the most important of the newly available isotopes emit only low-energy radiations, and special techniques and equipment were needed to assay them efficiently. Methods had to be devised to permit the reproducible measurement of samples that could be put directly into the sensitive detector volume without disturbing its basic characteristics. Ultra-thin "windows" were needed to reduce losses by absorption from samples external to the detector. Geometrical relations between the sample and the detector had to be arranged so that the latter would intercept as many of the emitted radiations as possible, while maintaining constant conditions of radiation scatter from the counting equipment. Counting "geometry" had to be high and strictly reproducible. Obviously, development in technique had to go hand-in-hand with the improved instrumentation.

A host of instrument manufacturers came into being during the early post-MED period. Competition was keen. Some companies foundered on technical inadequacies, others grew so rapidly that control passed from engineering to business management, apparently a necessity for large-scale survival.

B. Ionization Chambers

Ion chambers used in the laboratory are designed to measure activities in curies rather than exposures in roentgens, and so they are free from the constraints imposed on the design of an air-equivalent chamber (see section I C of this chapter). Then the size and shape of the chamber can be chosen to fit the particular job at hand.

Spherical chambers can be used when the size of the sample approximates a point source. Cylindrical chambers are more common primarily because of the ease of manufacture. In a cylindrical chamber, the sample can be mounted at one end of the sensitive volume so that essentially 50% of the emitted radiations enter the chamber (2π geometry). When mounted on a very thin film at the center of a cylindrical chamber, a sample can be assayed with nearly 100% or 4π geometry. In either case, the chamber dimensions are so chosen that all of the ionizations take place in the gas and not in the chamber walls.

In many assays, thin film mounts are required in order to obtain a high and reproducible counting geometry. Thin films reduce uncertainties due to back-scattered particles from the mount; they also reduce energy losses by absorption.

Since charged particle absorption is a function of specific mass, it is customary to rate films in equivalent thickness, usually $\mu\text{g}/\text{cm}^2$. For reasons of strength,

films of plastics such as formvar, nylon, and mylar replaced metals such as aluminum or thin sheets of mica. Films of $10 \mu\text{g}/\text{cm}^2$ can be made routinely, and thinner ones are possible (Yaffe 1962).

Although most ion chamber measurements are made at or slightly above atmospheric pressure, high-pressure chambers are sometimes used to increase ion absorption and reduce the size of the chamber needed to assay a given particle energy. Small windows of aluminum alloy about $4 \text{ mg}/\text{cm}^2$ will withstand pressure differentials of a few atmospheres.

C. Electrometers

Mechanical electrometers were quickly replaced by electrometer tubes. Long-term drift of the electrometer tube was still a problem, particularly if an attempt was made to add vacuum-tube amplifiers. The conventional or dc circuits amplified both the signal and all slow fluctuations and drift as well. If the original signal is oscillatory, it can be amplified by ac circuits, which do not respond to the slower variations.

The basic scheme for selective amplification was developed in 1938 for use with thermocouples, but nine years elapsed before it was applied to ion current measurements in the dynamic-condenser electrometer (Palevsky, Swank, and Grenchik 1947). The most popular design utilized a vibrating reed (whence the popular name) to produce a cyclically varying signal from the ion chamber, and this signal was then amplified by ac circuits. Ion currents on the order of 10^{-15} A could be measured with commercially available vibrating-reed electrometers. They enjoyed a short period of popularity until replaced with new instruments.

D. Proportional Counters

Electronic circuit components and designs continued to develop after the impetus of the MED declassification. The very stable power supplies needed for proportional counting were improved. Linear amplifiers with superior resistance to overloads were designed. Tanks of counting gas-quenching gas mixtures became commercially available, and most proportional counting was done with a slow gas flow following a rapid chamber flush after inserting the sample. Commercial competition was keen to provide the most reliable and easy to use equipment. Many improvements were unpublished because they were made by profit-oriented organizations.

Developments in the MED had added high- and low-energy discriminators to the basic linear amplifier. With these discriminators in use, only pulses falling within a narrow energy "window" were counted. Background counts were sharply reduced because these also were counted through the narrow window, and there was a corresponding increase in the overall sensitivity of the system. Beta-particle-energy spectra could now be obtained, an important advance in the identification and assay of radioisotopes.

When determining energy spectra, considerable counting time can be saved by the simultaneous counting of a number of energy channels instead of by the step-by-step movement of a single channel. A twenty-channel pulse height analyzer (PHA) was reported (Freundlich, Hincks, and Ozeroff 1947), the forerunner of later equipment made possible by borrowing computer technology.

E. G-M Counters

Steady, but unspectacular improvements in G-M tube and circuit performance continued as the demands for counting equipment increased. Scale-of-ten or decade circuits were developed (Regener 1946), which could be cascaded to provide scaled readings in the decimal system. Interpolation counts still had to be added, but the old $\times 64$ calculation of the binary scalers was eliminated. Still later, decade glow transfer tubes were produced, and the exact count could be read from glowing numbers without interpolation.

For many applications, halogen quenching gases (Liebson and Friedman 1948) replaced the organic quenchers. The halogens recombine after dissociation in the quenching process and thus provide a tube with an unlimited counting life.

G-M tubes were made in many configurations in order to maximize the geometrical efficiency of the assay. End-window counters and dipping counters were among the shapes available. The interest in ^{14}C assays, where only a 0.156-MeV beta particle is emitted, stimulated the production of thin entrance windows. These windows had to withstand substantial pressure differentials because the G-M tube has an internal pressure of only perhaps one-eighth of an atmosphere. Mica became a favorite window material. Sheets could be split to 1 mg/cm² or even a bit thinner. Mica-to-metal or glass seals were developed. Carbon-14 could now be counted with a fair, if not ideal efficiency.

F. Crystal Scintillators—Old and New

In 1903, Sir William Crookes, and independently, Elster and Geitel, discovered that crystals of zinc sulfide emitted tiny flashes of visible light (scintillations) when they were struck with alpha particles. This observation was quickly utilized by Rutherford, who used an arrangement known as a spinthariscopes in his classic studies of atomic structure.

Counting the tiny light flashes seen in a microscope is a tedious job, and crystal scintillators took on a much larger role following the development of the photomultiplier or PM tube (Larson and Salinger 1940). In the PM tube, a photo-sensitive cathode "sees" the scintillations in a crystal, and the resulting photoelectrons pass on to a series of electrodes each designed to emit several electrons for each one incident upon it. Stable current gains of 10^7 or so are readily obtained, with a strict proportionality between the number of electrons collected at the output and the number originally emitted by the cathode.

Hofstadter (1948) observed scintillations produced by the absorption of gamma photons in crystals of the alkali halides. In the case of alpha and beta particles, the magnitude of each scintillation is proportional to the energy deposited in the crystal, or the energy of the particle. Photons are absorbed by more complex mechanisms, but some fraction of the scintillations will correspond to the full energy of the photon, the fraction increasing with the size of the crystal. Thus, for all three radiations, the crystal scintillator can be used as an energy spectrometer.

Sodium iodide "activated" by a slight impurity of thallium, denoted by NaI(Tl) became the most popular crystal for photon counting. The Harshaw Company, among others, produced larger and larger crystals in quantity. NaI(Tl) crystals 25 cm in diameter are available "canned" with a PM tube in a thin, moisture-proof metal cladding. Organic crystals such as anthracene have been found most useful for beta-particle counting, and zinc sulfide is still preferred for alphas.

Scintillation counters quickly became very powerful analytical tools in radioactive assays. Using upper and lower energy discriminators, the emitted energy spectrum can be scanned in a succession of small increments and an energy emission distribution obtained. With these established, assays can be made with the system set to accept only one of the characteristic energies. The effect of background counts can thus be greatly reduced, since they also will be accepted only through the narrow energy window. Heath (1957) published an extensive catalog of gamma-ray spectra obtained with crystal scintillators. The exact spectrum obtained depends upon the size of the crystal, but cross-matching between two systems is usually easy.

G. Pulse Height Analyzers

Pulse shaping circuits and magnetic "memories" in which pulses could be stored were being produced for the computer industry, and these were quickly adapted to ion pulse counting. Sorting circuits routed pulses according to size to the various compartments of the memory. After an appropriate accumulation time, they can be retrieved to provide an energy spectrum of the incident radiation.

Technical progress steadily increased the number of memory channels in the binary sequence 128, 256, 512 . . . with corresponding increases in the resolving-power of the PHAs. At the same time, faster circuits permitted more effective utilization of the very short pulse lengths characteristic of a crystal scintillation counter. Heath (1966) updated his early compilation of gamma-ray spectra with records taken with the more modern equipment.

H. Liquid Scintillators—Carbon-14 and Hydrogen-3

When ^{14}C became readily available from Oak Ridge, its importance was quickly recognized, particularly in the fields of biology and medicine. The assay techniques then available for the 156-keV betas were far from satisfactory, and a large-scale attack on the problem was mounted. Ion chambers and G-M tubes provided only a partial answer.

Sample preparation was very important in order to minimize and standardize particle absorption in the sample itself. The carbon was sometimes converted to highly insoluble barium carbonate and counts made on the dried precipitate. A series of thin weighed samples could be counted and the specific activity (counts/mg) extrapolated to zero thickness to obtain the true value with no self-absorption. Alternatively, "infinitely thick" samples were counted under constant self-absorption conditions.

Some assay methods burned the sample, converting the carbon to CO_2 . This could be frozen out in a cold trap, the remaining gases pumped off, and the CO_2 warmed and transferred to a counting chamber.^(a) Carbon dioxide is not satisfactory for G-M tube operation, although some success was achieved by blending it with CS_2 .

The introduction of liquid scintillation counting (Raben and Bloembergen 1951) was literally a technical breakthrough. In principle, a scintillating molecule

(a) [See Figure PI-1.]

such as 2, 5-diphenyloxazole, quickly shortened to PPO, is dissolved in an organic solvent such as toluene, and the sample is added. Ions produced in the solvent molecules with no loss of energy due to window or self-absorption excite the PPO, and its scintillations are observed with one or more PM tubes.

In practice, preparation of the scintillating solution is more complicated. A "wave shifter" is added to match the color of the scintillations to the spectral response of the PM tubes. A secondary solvent is frequently needed to dissolve samples that are not soluble in the primary solvent.

Technical difficulties were quickly overcome, and liquid scintillation counting became the method of choice for soft beta emitters such as ^3H (tritium), ^{14}C , and ^{35}S . The method was also used for alpha-particle assays (Basson and Steyn 1954). Birks (1964) reviewed the early work.

Liquid scintillation counting has been refined into a very powerful analytical tool. The 18.6-keV beta particle of ^3H is readily counted at a specific activity of 1 pCi/g, ^{14}C at 0.15 pCi/g. Built-in data processing capabilities permit the simultaneous assay of two components such as ^3H and ^{14}C . Highly automated equipment has been developed for the unattended assays of large numbers of samples. Bransom (1970) and Harroden and Peng (1971) have provided reviews.

I. Semiconductor Detectors

Research on the properties of semiconductors, notably silicon and germanium, increased dramatically following the discovery of the transistor, and McKay (1951) reported on their use as alpha-particle detectors. Semiconductors have a high counting efficiency, producing one ion pair for about 3 eV of energy, which is only one-tenth the energy required in other detectors. That fact, together with their remarkable energy resolving capability, stimulated the application as radiation detectors, particularly in the field of gamma-ray spectrometry.

Extreme material purity is required for the satisfactory performance of a semiconductor, and early production processes were unable to achieve the ideal. Instead, controlled amounts of an acceptable impurity were deliberately introduced. Lithium ions were diffused through a germanium crystal to produce a lithium-drifted or Ge(Li) detector. Early Ge(Li) detectors were small, but, with improved techniques, sensitive volumes of 50 cm³ became commercially available. Ge(Li) detectors had to be maintained at liquid nitrogen temperatures at all times. Eventually, sufficiently pure semiconducting crystals were produced, and lithium drifting and cryogenic temperatures were no longer required.

Detector sizes are still relatively small, and the semiconductors find their greatest application in identification by spectrometry rather than in routine assays. Energy resolutions of 1 keV or so can be obtained, and these have been used to upgrade the gamma-ray energy catalogs (Heath 1974) previously provided by solid crystal scintillators.

J. Photographic Emulsions

Medical and industrial radiography are among the greatest consumers of photographic materials, and film badges form an important part of any personnel monitoring program. However, photographic methods now play a relatively minor role in most laboratories working with radioactive materials.

Nuclear track emulsions provide a unique method for precisely locating an alpha-particle emitter at the center of the outwardly radiating tracks. A similar technique has been used with soft beta emitters such as ^3H in tissue slices, but scattering limits its application to higher-energy betas. Very small amounts of activity can be located with emulsions because of the integrating effect of long exposure times and the amplification inherent in the production of a developable silver halide grain from a single ionizing event.

The technique is invaluable when needed, but it is time consuming and requires considerable patience and skill. This is particularly true in identifying and analyzing the tracks seen in the microscope. An early description of the method (Yagoda 1949) is still useful today.

K. Human Whole-Body Counters

Technical advances on many fronts led to the construction of counters capable of directly assaying gamma emitters contained in the human body. Larger and larger solid crystal scintillators were produced, and these could be looked at by either a large PM tube or an assembly of small tubes electrically aligned to produce summed pulses.

These large crystal volumes were quickly adapted to the measurement of gamma emitters present in the human body. A group at Argonne National Laboratory (Marinelli et al. 1961) developed a technique in which a single large NaI(Tl) crystal detected gamma rays with a reasonably constant geometry from all parts of the body. The crystal had a much greater volume, and hence sensitivity, than the G-M counters available to Evans (1937). In addition, the PHA equipment used with the crystal provided gamma-ray spectra for the positive identification of the emitters.

Large PM tubes were also used in the liquid scintillator whole-body counters developed as by-products of the search for the neutrino (Anderson et al. 1961). Here the human subject was surrounded by a cylindrical annular tank containing the scintillating solution, which was viewed by a battery of PM tubes. These tubes were connected to simple pulse-height discriminator circuits because the liquid lacked the energy resolution needed to operate a PHA. The liquid counter recorded from all parts of the body with about equal efficiency and had a high sensitivity because of the large volume of the detector.^(a)

Either type of whole-body counter had a high count-rate due to natural background, and heavy shields, usually of iron, were used to reduce it. Extreme precautions had to be taken to prevent contamination of the counting rooms.

These counters opened up new areas in the study of internal emitters. In a few minutes, a gamma activity of 1 nCi or so can be measured to an accuracy of a few percent. The amount of ^{40}K naturally present can be followed in health and in disease. In a few cases, notably ^{32}P , beta emitters can be assayed through the production of bremsstrahlung, but this method is not generally applicable.

Alpha emitters can be detected only if they are accompanied by gamma radiation. A case in point is the detection of ^{239}Pu through the 20-keV x rays emitted in a small fraction of the decays. Although these photons are strongly absorbed

(a) [The human whole-body counting device using this method was developed at Los Alamos.]

in the body, they are more penetrating than the more abundant alphas. Thin, large-diameter crystals of NaI(Tl) used inside a shielded room can measure ^{239}Pu down to perhaps 10 nCi (Voeiz et al. 1976) in a reasonable counting time. When the x rays originate at depth, as in the lung, calibration of the system is uncertain because of the strong attenuation of the soft photons.

The shielding required to attain the necessary background makes the whole-body counter a massive, expensive instrument suitable for installation in only a few large active laboratories. An ingenious adaptation is the shadow-shield counter, which can be transported, though with some difficulty, and operated in areas where onsite measurements are needed. In this counter, the NaI(Tl) crystal sees only a portion of the body at any one time, and this portion lies inside a massive shield. As the patient is moved (Parker and Anderson 1967) under the shield, the crystal scans the entire body under shielded conditions.^(a)

L. Absolute Counting

For many assays, such as most tracer studies, only relative counts are needed, to be expressed as percentages of some standard internal to the particular study. Such relative counting is comparatively simple requiring only standard sample preparation and a constant counting efficiency, or geometry.

Absolute counting is required in assays designed to establish body burdens and, thus, estimate the hazards associated with internal emitters. In many cases, a constant geometry can be established to count the samples against a standard certified by some laboratory, such as the NBS.

When the counting geometry is accurately known, as in the 2π or 4π proportional counter, the disintegration rate of the sample may be readily calculated from the observed count rate. Similarly, semiconductors may have an essentially 2π geometry for alpha particles if the sources are in the form of very thin films, perhaps formed by electrodeposition from solution.

Coincidence counting provides a powerful method for the absolute counting of radionuclides that emit more than one radiation per decay and whose decay scheme is accurately known. A beta decay followed by a gamma ray will serve as an example, although gamma-gamma or alpha-gamma coincidences may also be used. One detector that has a relatively high efficiency for beta particles and another responding only to gamma rays are required for the beta-gamma measurements. The circuits are arranged so that individual count rates of the beta and gamma detectors can be obtained. An electronic coincidence circuit is then introduced, which will record a pulse only when there are simultaneous ionizations (within about 100 nsec) in the two counters. Except for some few random coincidences, which can be allowed for, each gamma count will originate from the same decay process that triggered the beta detector. From these three measurements, with appropriate corrections for background, the absolute disintegration rate of the source can be calculated, without any prior knowledge of the efficiencies of the two detectors. Coincidence counting is a very powerful technique when it can be applied.

(a) [In chapter 12, we saw application of this type of device, in crude form, to measurements of the Marshallese.]

M. Low-Level Counting

Widespread demands have stimulated the quest for instruments and techniques capable of measuring ever smaller activities, or conversely of making measurements to the desired accuracy in shorter times. Equipment is at hand for counting individual ionizing particles and for measuring the energy transferred to the detector. Little progress can be made in this direction beyond arranging the counting geometry so that the detector will intercept as many of the emissions as possible, with a limit of a solid angle of 4π .

However, all counts are made in the presence of a background count arising from extraterrestrial cosmic rays, general terrestrial radioactivity, and from contaminants in the counting equipment itself. Any reduction in this background count relative to that from the sample will result in an improved precision in the net count, or in the counting time. If the background were strictly zero, a few pulses from a sample would be significant. Lacking the ideal, strenuous efforts have been made to reduce the background count in all types of assay systems.

In some geological formations, underground laboratories are useful. Counters may be located inside massive shields, provided that the shielding reduces more than it contributes. Steel produced before the advent of radioactive fallout is particularly useful because it is free of bulk contaminants. A thorough surface cleaning will remove all manmade emitters.

A battery of counters may be located around the one counting the sample and connected in anticoincidence with it. A pulse occurring simultaneously in a shielding counter and the sample counter will be rejected since it presumably was produced by a penetrating radiation arising outside the sample (NCRP 1978).

If the nuclide being assayed has a characteristic monoenergetic emission, as an alpha particle or a gamma ray, it may be counted with a narrow energy window, which will substantially improve the sample-background count ratio. Electronic circuits are now available (Oeschger and Wahlen 1975) that analyze the rising phase of each pulse and reject those not originating in the sample under study. As in the days of the Rutherford spinthariscopes, a few detectable ionizing events have become significant, but the amount of activity needed to produce them has been decreased by a factor of perhaps 10^{10} .

N. New Phenomena

Although advances in detection sensitivity, reliability, and assay speeds have been enormous, most of the measurements made today are based on radiation effects known for well over half a century. Ionization in gases, crystal scintillation, and photographic film darkening remain the workhorses of the field. Two recent additions to the methodology are worthy of mention.

1. Thermoluminescence

When certain crystals absorb ionizing radiation, some electrons will be raised into metastable energy levels where they will remain for hours or days. This trapping in excited states is in contrast to the very prompt return to the ground state of the electrons involved in the usual crystal scintillators. The metastable states can be relieved by heating the crystal, at which time all of the trapped electrons will return to the ground state. As in the case of prompt spontaneous fluorescence, photons of visible and ultraviolet light will be emitted. Thus, the process is known as thermoluminescence and the instrument as a TLD.

When the heating and the photoelectric recording of the emitted light pulse are carried out under carefully programmed laboratory conditions, the measured response can be related to the total amount of radiation absorbed by the crystal during the exposure period. After the light pulse has been recorded, the crystal can be put through a thermal cycle of "annealing" to ensure that all electrons are back in the ground state, ready to receive a second dose of radiation.

Some crystals, notably LiF and CaF₂, each with controlled traces of impurities, have radiation absorption characteristics very close to those of human tissue. This, together with the reusability, have made TLDs increasingly important in personnel dosimetry. Attix (1972) has provided a useful review of the field.

2. Particle Track Etching

Neutrons, alpha particles, and heavier charged particles such as fission fragments, produce some structural damage when moving through solid materials.

The damage centers are very small, but they can be enlarged by chemical etching with NaOH or EDTA (ethylene diamine tetra acetic acid) to produce tracks visible in the microscope (Fleischer, Price, and Walker 1965). The number of tracks per unit area can be related to the total number of particles incident on the material. Certain plastics, glasses, and ceramics have been found useful. The technique is specialized, but it has been applied to biological dosimetry (Becker 1969).

IV. Summary and Commentary

This chapter reviews almost a century of development of radiation-measuring instruments. Obviously, the field had had almost forty-five years of development before 1940. Nevertheless, the needs of the Manhattan Project posed formidable problems for the instrumentation groups. Because of the high security classifications and to explore several avenues simultaneously, the several laboratories, e.g., Berkeley, the Metallurgical Laboratory in Chicago, the Los Alamos and Oak Ridge groups, and the project at the University of Rochester, had specific tasks in instrumentation, as well as in their research. New and unique circuitry was developed. Instruments for radiation safety purposes developed beside the more conventional laboratory measurement devices. In some cases, the instruments from the different laboratories followed different routes to the same end. At the end of World War II, when declassification made it possible for the laboratories to share and compare their products, there was some inertia toward continuing to use the familiar methods, and even to defend their superiority. As the commercial instrument makers gradually took over design and manufacture of radiation-measuring instruments and numerous symposia were held, this tendency abated.

In the period after World War II, there was, of course, an explosive expansion of the uses of radioactive materials in all branches of the natural and biological sciences. Tracer chemistry and nuclear medicine put demands on instrumentation far beyond what they would have been had the needs been only the researches described in this book. These needs and the chances for handsome financial returns brought not only improvements but essentially new devices. Among these are the scintillation counter using special solid crystals, the liquid scintillation counter, and a large expansion of the ability to do pulse height

analysis and draw complete spectra over a range of energies. The discovery of the transistor made possible very considerable reductions in size and power requirements.

Perhaps some of the most striking developments in the counting of radioactivity in the past two decades have been from uses in nuclear medicine. These devices are not described in this chapter since it was considered wise to review them briefly as part of the story of nuclear medicine in chapter 20. Scanning, imaging, and recording have developed enormously. Now, with the aid of computer print-outs, all information except suggested diagnosis and treatment can apparently be automated. While these developments have been primarily for clinical installations, the techniques have, of course, spilled over into the research laboratories. Now a day or a week can produce more and better radioactivity analyses than could have been generated in a year with the old hand-operated instruments. Unfortunately, with this has come a gulf between the researchers and knowledge of the reliability of their results. This can be bridged only by confidence in the manufacturers and their service representatives or an inordinate investment of time and energy by the researcher.

Capsule Chronology

Prior to 1930 A few field measurements made by cosmic-ray physicists. The spinthariscopes developed. Many instruments built for portable use in medical installations, e.g., Victoreen R-Meter, film badges.

1929 Taylor portable survey meter.

1930s Some field-type instruments developed as modifications of laboratory instruments, e.g., Geiger-Müller counters, film badges. In general, better for external sources than measurement of radionuclides.

Evans adapts count-rate circuitry to a mobile machine, develops a double ionization chamber for radon, and an ac-operated device for thoron (Evans and Goodman).

Expired air analyses for radon and thoron made using gold-leaf electroscope.

1940s MED^(a) uses electrostatic precipitator and suitable detector for measuring airborne activity. Also static evacuated sampling flasks for grab samples that are subsequently analyzed in the laboratory.

MED adapts use of filter papers, as used in industrial hygiene, to measurements of radioactivity. Leads to development of continuous air-monitoring devices with collection and measurement assembled in one unit.

MED develops many devices with code names because of security restrictions. Examples:^(b)

"Pee Wee," a heavy, bulky air-proportional counter used at Los Alamos and Berkeley for alpha surface contamination monitoring.

"Juno," a large ionization chamber with a thin window for alpha or beta-photon monitoring of bench tops, etc. (Note: the "Juno" with appropriately modernized circuitry is still being manufactured.)

"Poppy," an alpha counter using a photomultiplier tube and scintillation counter. Audible clicks can be replaced by count meter.

"Samson," like Juno, but intended for alpha-particle measurements only.

"Cart poppy," an ac-operated, more stable, more bulky version of the Poppy.

"Pluto," an instrument developed especially for monitoring of plutonium and related alpha-emitting radionuclides. The allusion to the highly classified radionuclide, plutonium, produces an outburst from General Groves.

"Sniffy," an air monitoring device.

Cascade impactor developed in U.K.—adapted to U.S. operations in late 1940s.

(a) [For abbreviations and acronyms, see Appendix D.]

(b) Many other picturesque names were applied to other instruments used for radiation exposure or dose determination, rather than for radionuclide detection and measurement, e.g., "Cutie Pie," "Chang and Eng," "Paint Pail," "Zuto," etc.

Marked improvements made throughout the period, including thin-window counters, Schmidt trigger circuit, thyratrons, flip-flops, uni- and multivibrators, binary and later decade scalers. Use of small high-resistance, low-current drain tubes, developed originally for hearing aids and lower voltage G-M tubes. (See also chapter 17.)

1950s Air sampling and monitoring devices change little except for addition of spectrometry.

Two-stage sampling devices introduced instead of cascade impactor as less complex and easier to use.

Moving filter air monitor developed.

Continuous gas monitors developed for low levels of beta emitters. Called "Sniffers."

Midget cyclone developed.

Development of scintillation techniques makes continuous monitoring of radon concentrations easier.

Beginning of working level measuring systems for radon and daughters (Kusnetz).

Search for thinner and thinner windows for alpha instruments.

Search for new quenching gases.

1957 Lucas cell developed for measurement of grab samples to be analyzed for radon and progeny.

Portable gas flow proportional counter developed for alphas (Eberline).

1960s Air monitoring for plutonium developed using semi-conductor detectors, now the mainstay for monitoring plutonium in work-room air.

1963 Portable whole-body counters taken to Marshall Islands (Cohn, Brookhaven).

Truck-mounted shadow shield whole-body counters developed at Hanford and later go into general use, including in the Arctic.

Mid-1960s Radon film badge.

1969 Development of FIDLER, a scintillation detector for large area surveys of outdoor surfaces.

1970 Two-filter method for radon and radon daughters.

Integrating working level meters appear.

1971 Track-etch techniques for alpha particle monitoring.

1973 ANSI adapts Kusnetz method for monitoring uranium mines.

"Instant" working level meter developed (Groer, Evans, Gordon).

1977 Other working level measurement systems developed (Schiager, Shreve, et al.).

1980s Miniaturization, almost exclusive use of solid-state circuitry, reliability improvements.

Chapter 18

Instrumentation for Monitoring and Field Use^(a)

*by Ronald L. Kathren, Battelle, Pacific Northwest Laboratories
Richland, Washington*

Overview

In this chapter, the evolution of field instrumentation for the detection and quantification of internal emitters is traced. The history of field instrumentation largely begins (and to some extent ends) with the Manhattan District, for, prior to that time, there was little impetus for field measurements of internal emitters. Those halcyon few years of the Manhattan District were marked by an intensity of development and discovery that clearly set the stage for what was to follow, as even the casual reader should not fail to note. Perhaps the excitement and zing faded in later years, but the basic concepts for field instrumentation first put forth in the forties remain.

This brief chapter shows how the knowledge of the hazards of internal emitters gained in the laboratory was applied to field measurements to ensure the safety of those working in the laboratories and production facilities, and thus provides an interesting counterpoint to the main theme of our book.

(a) As used in the context of this chapter, field measurements are those that are made outside of the laboratory, normally in the workplace or the environment and generally for radiation protection purposes. Thus, field instrumentation implies a degree of ruggedness to permit transportability to and use in situations in which various environmental conditions (e.g., temperature, humidity, supply voltage) are uncontrolled. Monitoring instrumentation is instrumentation used for measurement (as opposed to sampling) under diverse conditions, in the plant, laboratory, or in the field.

The term "direct counting" refers to counting of the sample with no pretreatment or radiochemistry of any kind. Direct counting thus applies to situations in which the sample, as it is collected, is counted in situ in a monitoring device or where a sample is collected and simply brought into the laboratory for counting. Samples that undergo dissolution, chemical separation, or dilution would thus not be considered to be directly counted.

I. Before the Manhattan Engineer District

In the historical record, the Manhattan Engineer District (MED) marks the real point of origin for field measurements of radioactivity, particularly in living organisms, although there was some effort in this regard before 1940. Prior to about 1930, radiological measurements were largely confined to the laboratory, although exceptions did exist. Physicists studying cosmic rays travelled to various parts of the world, their major field instrumentation consisting of thick photographic emulsions or large, bulky electrometers and Geiger-Müller (G-M) tubes with associated electronics. Some field measurements had also been made of naturally occurring terrestrial radiations and radioactivity, using basically the same techniques and instruments. Common practice, however, was to obtain a sample of the environmental medium of interest by whatever convenient means and transport it to the laboratory for analysis. What instrumentation was available was largely used in the laboratory and, if taken into the field, as was sometimes done, was used in a manner that was largely an extension of laboratory techniques and not in the sense of an instrument capable of independent operation under field conditions.

Genuine interest in field measurement of radionuclides began as the hazards of internal radium began to be recognized. This interest was primarily in measurements of radioactivity in the environment. By contrast, laboratory measurements also included detection and quantification of radioactivity within the body. As the tragic story of the dial painters unfolded, the need for instruments to determine radiological conditions directly in the field was recognized, but, on the eve of the entry of the United States into World War II, there was precious little field instrumentation applicable to the detection and measurement of radioisotopes either in or out of the body. The few field measurements that were made were usually accomplished with laboratory instruments brought into the field for ad hoc use and hence were simply extensions of laboratory operations. There was but a single commercially available survey meter—a Geiger-Müller instrument constructed by Victoreen Instruments—and this device was not particularly suited to contamination monitoring (Kathren 1980; Terry 1980). This lack of field instrumentation is not too surprising, for there was no real basis or need for quantitative field measurements, given the lack of standards for permissible concentrations of radioactivity in air and water or as surface contamination. The first such standard—10 pCi/l for airborne radon—was proposed in 1940 and incorporated into *National Bureau of Standards Handbook 27*, issued May 2, 1941, which later became Report No. 5 of the National Committee on Radiological Protection (Evans 1980).

II. Early Evolution of Field Instrumentation

As alluded to above, fully a quarter of a century after the discovery of x rays and radioactivity, only a handful of instruments had been devised for measurement of radioactivity and radiation levels in the field. Perhaps the oldest of these instruments was the spinthariscopes, devised by Sir William Crookes in the early 1900s (Crookes 1903). This simple device was a small, light-tight metal tube about an inch in diameter and a few inches in length fitted with a ZnS screen at one end and an eyepiece at the other. A small quantity of an alpha-emitting material, such as a uranium-bearing mineral or compound of radium, could be placed directly on the screen, and the resulting flashes of light or scintillations

produced in the ZnS could be observed through the eyepiece in a darkened room. Quantitative measurements could be made by simply counting the number of flashes in a given time period and correlating them with the amount of material present.

Crooke's spinthariscopes were used for a half century, and for many years these simple passive devices enjoyed not only applications as a tool for scientists but also as entertainment for the general public, who purchased them in large numbers for parlor displays of the phenomenon of radioactivity. However simple and crude, it seems to have been the only true field instrument for measurement of radioactivity for many years. Early field measurements were ordinarily concerned with quantification of radiation sources such as x-ray machines (as opposed to radioactivity)^(a) and were generally applied to the radiotherapy setting. Thus, in the 1920s, the familiar condenser ionization chambers made their appearance with the most familiar American-made unit, the Victoreen R-meter, becoming available in 1927 (Victoreen 1944). Photographic films were used for routine personnel monitoring at least as early as 1921, often taking the form of a small piece of film or dental x-ray packet partially covered by a penny or paper clip (Pfahler 1922). The first true film badge was devised a few years later by New York radiological physicist Edith Quimby who used metal filters to compensate for the variable sensitivity of the photographic emulsion as a function of x-ray energy (Quimby 1926).

The first portable survey meter made its appearance in 1929. It was developed by Lauriston Taylor, then of the National Bureau of Standards (NBS), to monitor his own potentially hazardous exposure to an x-ray beam (Taylor 1967). This device was equipped with three interchangeable chambers of different sizes to allow for measurement of various intensities and was in every sense a true field instrument. It had, however, no application to internally deposited radionuclides (colloquially referred to as internal emitters), being useful only for measurement of external radiation fields.

Interest in field measurements of radionuclides, specifically radium, grew in the 1930s, fueled in large measure by the tragic deaths of wealthy Pittsburgh industrialist Eben M. Byers, a consumer of a radium-containing patent medicine, and the radium dial painters. The decade of the 1930s saw the birth of in-vivo counting and also the development of radon breath analysis along with the numerous improvements in laboratory instrumentation. Major advances in counting electronics were made including basic scaling circuitry, first built by the British physicist C. E. Wynn-Williams in 1932 (Wynn-Williams 1932), based on the so-called flip-flop circuitry or Eccles-Jordan trigger, which made its appearance in 1918 (Eccles and Jordan 1919). Geiger-Müller detectors were greatly improved, and in the mid-1930s, Robley Evans and his coworkers at Massachusetts Institute of Technology (MIT) adapted the count rate circuitry to practical use making possible field survey and counting instrumentation. Among the first applications was a portable direct reading random pulse count rate meter equipped with a G-M tube as a detector used by Evans in his studies of radium metabolism in man (Evans 1980).

The MIT counting rate meter, as it was then termed, was first described in 1936 (Gingrich, Evans, and Edgerton 1936) and was basically an electronic amplifier and computing circuit with dc current or voltage output proportional to the number of pulses fed into the circuit via a G-M tube. As the early G-M

(a) Gamma rays from radium or the radium decay chain were the notable exception.

tubes were not self-quenching,^(a) the preamplifier was used for quenching (Kip and Evans 1941; Kip et al. 1946). Pure hydrogen, which has no metastable states, was also recommended as the fill gas to avoid the quenching problem (Duffendack, Lifschutz, and Slawsky 1937). Subsequent improvements included a strip chart recorder and an internal calibration circuit based on a multivibrator pulse generator synchronized to various multiples of the 60-Hz line frequency. While obviously not a field instrument per se, the MIT counting rate meter circuitry was amenable to adaptation to battery power and to use in portable instruments and was therefore in effect a historical antecedent of numerous instruments developed for use in the field. Another important contribution of the MIT group to both laboratory and field measurement problems was an early and thorough consideration of the statistical aspects of count rate meter results (Schiff 1936; Schiff and Evans 1936). This work was in part the product of the same Robley Evans, who figured so prominently in the studies of the radium dial painters, and his colleague, Leonard I. Schiff, who became well known for his contributions to theoretical physics and quantum mechanics, and, in conjunction with the theoretical evaluation of scaling circuit statistics published the following year (Alaoglu and Smith 1938), provided an important underpinning to the application of instrumentation to measurement of low-level radioactivity in the field.

Other circuitry was developed to provide solutions to the quenching problem. C. E. Wynn-Williams patented an external quenching circuit and also constructed G-M tubes capable of satisfactory operation at only 300 V (Lewis 1943). The Wynn-Williams circuit used a thyratron to drive a recording counter. Multivibrator circuits were also used for external quenching, and a significant body of literature developed on the theory and practice of external quenching by electronic circuitry.

Perhaps the single field measurement for internal emitters that was well developed prior to World War II was the so-called breath analysis, or analysis of the exhaled air for both radon and thoron. In his pioneering studies on the metabolism and fate of ingested radium, Evans determined a relationship between the amount of radium in the body and the quantity of radon in the expired air (Evans 1937). Initially, radon was measured by collecting the expired air in an ionization chamber attached to a gold-leaf electroscope; subsequently, the method was improved to include electrostatic collection (Aub et al. 1952). More recent techniques include having the subject blow up a balloon, which is then examined for long-lived radon daughters. The original gold-leaf electroscope technique was used in the field by the University of Missouri from 1930 to 1936 for detection of thoron in the expired air of mesothorium (i.e., ^{226}Ra , ^{228}Ac) workers (Morris 1938).

III. Air Sampling and Monitoring: MED

In general, until the MED was organized in the early 1940s, field sampling and measurement of internal radioactivity hazards were largely carried out by industrial hygienists and perhaps an occasional physicist using the standard collection techniques of the time for measurement of nonradioactive dusts (Drinker and Hatch 1947) (see figures 18.1 and 18.2). These included dust collection via

impingers of the Greenburg-Smith and other types with subsequent particle and radioactivity counting, or the use of electrostatic precipitators to obtain a dust sample, which could then be counted for radioactivity in the laboratory. One technique specific for field sampling of thoron daughters was developed at MIT (Evans and Goodman 1940); it utilized an air mover to deposit the dust-borne daughters of thoron (i.e., ^{212}Pb and progeny) onto planchets, which were then returned to the laboratory for analysis (Evans and Goodman 1940). Thus, on the eve of the formation of the MED, field instrumentation for sampling and measurement of radioactivity in the workplace or the environment gave no hint of the heightened interest and dramatic changes that would take place over the next few years.

Electrostatic precipitators were better suited to field measurement of radioactive dusts than impingers since the material removed from the air was deposited dry on the inner surface of the cylindrical metal precipitator tube and could be directly and easily measured in the field if necessary with a G-M detector

inserted directly into the precipitator tube. Collection with Greenburg-Smith or similar impingement devices was necessarily wet, often requiring relatively lengthy laboratory analysis with concomitant delay. The standard impinger had a fairly high sampling rate—11.5 ft³/min—but the overall efficiency of the collection and counting system was low, typically only 0.5% (Nickson 1951).

Electrostatic precipitation was thus a preferred air sampling method during the early days of the MED (Morgan 1948). The typical electrostatic precipitator was a standard commercially made ac-powered unit weighing approximately thirty-one pounds. Samples collected with this device could be used for measurement of alpha as well as beta-photon emitters depending on the type of detector used for readout. Common practice was to collect the sample in the field and take the precipitator tube to the laboratory for a timed count using a binary scaler.

Also used in the early days of the MED were static evacuated sampling flasks known as vacuum cans or pigs (see figure 18.3). These appropriately named metal devices provided the means of obtaining a grab sample of a known volume of room air, which could then be counted for beta-photon activity in the laboratory with a G-M detector. Another use of the evacuated can was for the collection and analysis of samples of radioactive gases such as ⁴¹Ar. Sampling was in the field followed by laboratory analysis, which was accomplished by connecting the metal can to an electrometer (Morgan 1949).

FIGURE 18.3. Counting system for gas and particulate air samples, dating from Manhattan District days. A portable gas sampling flask, commonly called a pig, is shown in the lower left. (Photo courtesy of Pacific Northwest Laboratory.)

An important contribution of the early MED to field instrumentation for internal emitters lay in the application and development of air sampling techniques involving the removal of particulate radioactivity from an air stream with filter papers, which could then be directly examined or counted in the laboratory with G-M tubes or other detectors. To be sure, the filter sampling techniques did not originate in the MED but had been used previously by industrial hygienists for nonradioactive dusts (see figures 18.3, 18.4, 18.5). Although in many respects not particularly well-suited to nonradiological applications, except perhaps for gravimetric dust measurements, the filtration method was almost perfectly suited to evaluation of airborne radioactivity. Initial techniques

were quite simple and involved a simple air mover such as a vacuum cleaner motor pulling air through a standard laboratory filter paper on which the air-borne dust was collected. Both the filter technique and electrostatic precipitation were found to be satisfactory for routine use in sampling workroom air, although the potential errors associated with samples collected outside the breathing zone were recognized (Nickson 1951). Moreover, both types of samplers were used on a spot-check as well as continuous basis, both within the plant and in the plant environs (Cantril and Parker 1945; Morgan 1948). Continuous air sampling and monitoring were also routinely accomplished on gaseous effluent lines.

FIGURE 18.4. (Right) Entering a radiation zone during Manhattan District days. The instrument in the foreground is a portable air sampler, the air mover motor is mounted on the little wheeled cart and draws air into the duct, which begins just to the left of the door knob, down through a filter housed in the box near the knee of the monitor. (Photo courtesy of Pacific Northwest Laboratory.)

FIGURE 18.5. (Left) An air monitoring system dating back to the Manhattan District. (Photo courtesy of R. L. Kathren.)

The basic continuous air monitor used in the MED evolved about 1944 and consisted of several individual components connected together to provide an integral unit (see figures 18.3 and 18.5). Air was drawn continuously through a paper filter by a vacuum cleaner motor. The filter was rolled into a cylinder around a G-M tube and was directly counted for beta-gamma radiation as the dust was collected. To increase sensitivity and minimize interference from background radiation, the filter and G-M detector assembly were housed in a lead-shielded enclosure. The signal from the detector was generally fed into a count rate meter, which in turn drove a standard commercial recorder (Morgan 1948, 1949). Modern air monitoring equipment is essentially identical conceptually, although more sophisticated detectors, electronics, and alarm systems are in use.

Collection of alpha activity in air was generally accomplished by electrostatic precipitation. The alpha-bearing airborne dust was deposited on a thin aluminum sheet lining the inside of the collecting cylinder. This sheet was removed carefully after the sampling period and taken to the laboratory where it was counted by alpha proportional counters (Morgan 1950).

Despite its many technical advantages, air sampling by electrostatic precipitation never was a highly popular technique. The necessity for cleaning the collector was a minor inconvenience. More troublesome were the need for ac power as well as the relatively large bulk and weight of the instrument—more than 20 kg in some instances—and the inconvenient and disconcerting arcing that occurred during the collection procedure, particularly in humid atmospheres.

IV. Electronics and Counting Instrumentation

To a great extent, evaluation of radionuclides in the field was facilitated by the advances in electronics and counting instrumentation that devolved from the MED and that have been detailed in two of the volumes of the National Nuclear Energy Series (Rossi and Staub 1949; Elmore and Sands 1949), chapter 17 herein, as well as in numerous internal and open literature reports. These experimental efforts led to the development of reliable and reproducible counters such as a thin-walled G-M tube designed at the Metallurgical Laboratory for use as a beta counter and the thin mica end-window G-M tube. Both of these, but in particular the latter, were extremely useful for counting samples of radioactive dust removed from the air and were quickly applied to this purpose. In general, alpha counting of air samples in situ was not accomplished with early field instrumentation, although appropriate detectors were potentially available.

Another significant advance was the development of practical scintillation detectors (see chapter 17). Initially, the scintillation phenomenon had been used by Rutherford and other pioneers who observed and counted individual scintillations with the aid of a microscope, a difficult, tedious, and error-prone procedure. By 1930, scintillation counting was replaced by G-M counting, which offered greater flexibility, accuracy, range, and other advantages. But about 1940, interest in scintillation counting was rekindled by the development of the photon-tube counter, a hybrid detector that joined a scintillator to a photo-sensitive G-M tube (Krebs 1955). Further work with scintillators in the latter days of the MED led to the development of the modern scintillator-photomultiplier combination (Curran and Baker 1944), which has been widely utilized for

detection and measurement of radionuclides of concern in the field. For alpha-emitting radionuclides, ZnS, operable at room temperatures, quickly became the detector of choice (Ahearn 1948, 1949) and to this day is still widely used for detection of alpha contamination from plutonium and other important radioisotopes in the field.

For beta and photon counting, the G-M tube remained the primary detector. Solution of the quenching problem (chapter 17) led to the ability to use G-M detectors at higher counting rates, ranging to 10^6 counts per minute. Organic quenched tubes were widely used throughout the 1940s but showed a finite lifetime just as did the laboratory instruments because of dissociation of the organic component of the fill gas. This problem was overcome to a great extent by use of halogen-quenched tubes, which made their appearance during the 1950s.

The electronics advances in other areas were in many instances truly striking. Among these were the Schmidt trigger circuit, a type of voltage discriminator that made possible fast counting and was widely used as the basis for several of the "standard" counters that were developed during the war. These included the Model 220 and Model 600 counters. The Model 220 counter was designed to use only miniature tubes and thus was especially suited to portable applications. The Model 600 counter was designed for higher counting rates, and featured a scale of eight (i.e., three consecutive Schmidt triggers) based on the design by Shepherd and Haxby (1936), with a resolving time of only $0.7 \mu\text{sec}$ (Sands and Elmore 1949). Other triggering circuitry was also developed and used including thyratrons, and various flip-flops, univibrators, and multivibrators.

Triggers were, of course, applied to scale-of-two circuits, giving rise to widespread use of the binary scaler. Also developed during the war years was a satisfactory scale-of-ten or decade scaler, which provided the count data in the far more convenient decimal readout. This circuit consisted essentially of a scale-of-sixteen circuit plus an additional flip-flop, which was designed to cut off the upper six counts, permitting operation as a scale-of-ten device. The output from either the first or subsequent decade was used to drive an electro-mechanical register, which produced a direct decimal readout of the number of counts, thereby obviating the need for conversion from the binary readout and reducing errors (Elmore 1949; Sands and Elmore 1949) (see figure 18.6). A commercial decade scaler based on this circuitry was available at least as early as 1947, offered by the Potter Instrument Company of Flushing, New York. This device was designed to operate with G-M tubes and featured three plug-in type decades and a resolution time of $5 \mu\text{sec}$ (Nucleonics staff 1948).

FIGURE 18.6. An early decade scaler, of commercial manufacture, circa 1950. Although equipped with a handle, this ac-powered unit was not specifically designed for field use. (Photo courtesy of R. L. Kathren.)

Other electronics developments of significance to field measurements of radioisotopes during the war included improvements in linear voltage amplifiers, which, when taken together with the improved detectors, provided a greatly enhanced field monitoring capability. One such amplifier was a relatively simple ac-operated dc amplifier, which was found to be quite useful in the workplace for continuous monitoring purposes using an ionization chamber detector. This amplifier used only two vacuum tubes, both pentodes, and provided an output signal suitable for driving a standard commercial 1 mA recorder (Elmore 1949).

The discovery of the transistor and the development of solid-state electronics were important quantum jumps for field monitoring. The solid-state revolution not only made possible smaller lightweight instruments with improved reliability and freedom from environmental factors, but also eliminated dependence on ac power or heavy battery packs. Thus, an entire new family of hand-held contamination-monitoring instruments began to evolve during the 1950s. By mid-decade, these were featured in commercial lines of instrumentation, and the venerable workhorses, such as the cart poppy (figure 18.7) and Pee Wee, began to be replaced by smaller and more reliable units. Alternating-current-powered transistorized rate meters used as laboratory bench monitors or as station monitors for monitoring personnel exiting radiation zones also appeared in the middle 1950s, with the Hanford designed "Scintran" in the vanguard. The name "Scintran" was derived from the words scintillation and transistor; the

FIGURE 18.7. An early (circa 1945) cart-mounted ac-powered alpha survey meter for field use. Ac power was required to achieve the requisite stability for the air proportional probe shown atop the unit. (Photo courtesy of Pacific Northwest Laboratory.)

Scintran was a transistorized rate meter equipped with audible variable set alarm and ZnS scintillation detector that was designed for use as a personnel alpha-contamination monitor. Solid-state electronics, coupled with solid-state detectors, also led to development of an alpha air monitor suitable for detection of maximum permissible concentration (MPC) levels of plutonium about 1960 (Lindeken and Phillips 1961).

V. Later Developments in Air Monitoring

Within a few years after the close of World War II, field sampling and monitoring for airborne particulate radioactivity were fairly standardized and more or less routine operations. Typical methods were described in the open literature, with particles in air most conveniently and commonly sampled by means of various types of filters, usually glass fiber or cellulose acetate. Common practice for grab samples was to use a high-volume air sampler, which drew air through a filter with an area of 10 to 20 in.² at a rate of 30 to 70 ft³/min (figure 18.8). These samplers used commercially available vacuum cleaner motors (Schulte and Hyatt 1954). There has been substantially little change in this technique over the years.

FIGURE 18.8. A portable high volume air sampler in use at the Hanford Laboratories about 1955. Substantially the same instruments are in use today. (Photo courtesy of Pacific Northwest Laboratory.)

For continuous air sampling, a commonly used technique was based on the adaption of a standard commercial vacuum cleaner (the Filter Queen) to draw a sample of air through a 4 x 9 in. filter paper at a flow rate of 4 ft³/min. Constant air flow was maintained with a variable orifice regulator (Schulte and Hyatt 1954). Numerous other samplers were also used, but almost all were based on air filtration; electrostatic precipitation, impaction, and impingement techniques were only occasionally used, if at all.

Indeed, by 1950, the basic design for continuous air samplers and monitors for particulate radioactivity in air that would be used for the next three decades was, for all practical purposes, fully developed. Granted that monitors would become smaller with the advent of transistors and solid-state circuitry and that some sophistication would be achieved through the use of spectrometry. But all in all, the basic methods would not be appreciably changed; in more than one instance, the commercial particulate radioactivity monitor of 1950 would be very

similar in both physical appearance, design, and capability to its modern descendant of the 1980s, perhaps even to the extent of utilizing identical components such as air movers and detectors.

An exception to the above generalization was the development of a constant monitor for plutonium in air, which occurred in the early 1960s. This was made possible by the development of high-resolution solid-state semiconductor detectors which, when used in conjunction with a single-channel analyzer, allowed for relatively good differentiation of the 5.15- and 5.13-MeV alpha particles associated with plutonium decay from alpha particles of other energies associated with the decay of radon daughters. Early devices of this type were subject to significant interference from radon daughters, but still were able to detect one MPC of plutonium in air in a typical eight-hour work shift (Phillips and Lindeken 1963). Subsequent improvements in both resolution and sensitivity of the detectors and associated electronics made possible sophisticated background suppression techniques, which enhanced sensitivity by about a factor of two, but greatly increased reliability and reduced false alarms.^(a)

The solid-state alpha spectrometry monitoring device for plutonium in air has remained essentially the same for about two decades, although in recent years considerable attention has been given to other techniques. A mass spectrometry technique has been developed (Nielsen 1976) but has not yet proven practicable for routine operations because the small sampling rate (0.6 l/min.) results in a very low probability of encountering a plutonium-bearing particle. Virtual impaction techniques in which the larger particles are impacted at each stage into a slowly moving air stream, which is then filtered and counted, show promise and are about ten times as sensitive as the conventional alpha spectroscopy techniques developed in the early 1960s (Yule 1978; Loo, Jaklevic, and Goulding 1974).

Although the importance of particle size was recognized during the MED days, it was not until after the war that practical field instruments and techniques made their appearance (Stokinger and Laskin 1950). Prior to the development of the cascade impactor in the mid-1940s, impingers and electrostatic precipitation were the major instruments available, and these had serious limitations, not the least of which was varying and frequently unknown efficiency for different sized particles. The actual determination of size was also subject to gross errors and was commonly done by optical microscopy techniques.

The cascade impactor is a multistage sampling device that passes the air through a series of jets or orifices of continually decreasing size at right angles to each other (May 1945). Streamline design and the use of rectangular orifices produced high collection efficiencies for the various sized particles that were

(a) The plutonium-in-air monitor provides a clear illustration of technology transfer and how the development fruits of the government-funded national laboratories encouraged and spun off private industries: In 1967, Edgar Beard, a technician at what was then the Lawrence Radiation Laboratory at Livermore, left the Lab to form a company centered around the manufacture and sale of this device. Ironically, one of his first (and perhaps even his first) orders for the commercial version of this device came from another Atomic Energy Commission (AEC) laboratory. Over the years, RaDeCo, the company that Ed Beard initiated as a cottage industry, manufacturing the first units in his garage, made many improvements on the original device and expanded into other product lines as well, using many public-domain government developments. The history of RaDeCo is a typical American success story; the prosperous company was ultimately sold and is now a division of SAI Incorporated.

collected on oiled slides, deposition resulting from the inability of the particle to follow the tortuous movement of the airstream because of the high relative momentum of the particles and the low viscosity of the air. Several overlapping size distributions were obtained, which were determined by direct microscopic examination. The original model was quickly improved and adapted to field use (Sonkin 1946; Laskin 1946).

Multistage impactors, although a significant improvement over thermal precipitators, konimeters, and impinger and electrostatic precipitator methods, were not widely used, partly because of their inconvenience and potential inaccuracy and the high degree of skill required for their use. Practical improvement was sought through the use of two-stage rather than the typical four- to six-stage impactors. The importance of particle sizing was underscored in 1952 independently by Eisenbud and Davies, both of whom suggested the use of two-stage sampling devices for radioactive dusts (Eisenbud 1952; Davies 1952).^(a) In 1953, several new particle size devices were proposed. One of these was the Hexhlet, which was a horizontal elutriator followed by a filter that seemed to have appropriate sizing characteristics since it followed the theoretical penetration curve proposed by Davies (Wright 1954). Other two-stage devices were also proposed, several of which utilized a small cyclone as the first stage (Watson 1953; Harris and Eisenbud 1953) and another that used a preimpinger (May and Druett 1953). The improved cascade impactor enjoyed some popularity during the 1950s, and the May preimpinger device and midget cyclone were first employed in the late 1950s (Hyatt 1960). Subsequent applications have included various improved multistage impactors, which is the instrument of choice today for field studies of particle size (Healy 1970).

Another field method for continuous monitoring of airborne radioactive dusts was the moving filter air monitor (Kuper, Foster, and Bernstein 1950). This device made its appearance in the late 1940s and consisted of an electromechanical device designed to continuously advance a strip of filter paper across an aperture through which air was being drawn. The rate of movement was sufficiently slow—one inch per hour was typical—that a volume of several cubic meters of air was drawn through any given portion of the paper strip during its traversal of the aperture. After collection of the dust, the tape was then passed in front of one or more detectors. Thin end window G-M tubes were typically used for beta-gamma counting, and if alpha counting was also to be done, a ZnS scintillator was commonly used. Depending on the adjustment of the rate of advance of the tapes and other mechanical factors, counting was generally accomplished about a half hour to as much as eighteen hours after the sample was collected.

The moving filter air monitor provided certain advantages over a static constant air particulate sampler. The relatively short sampling time for any given part of the filter eliminated the problems associated with dust loading and build-up on the filter and ensured a relatively constant sampling rate. Background counts attributable to natural radioactivity in the air were minimized, which permitted a more rapid and sensitive analysis for artificially made radio-nuclides. By use of two or more sequential counters, decay data could be automatically obtained by comparison of the counts; the interval between the

(a) [It was planned that the two stages represent respirable and nonrespirable size ranges respectively, or particle sizes that would deposit preferentially in the upper respiratory tract or the lower respiratory tract.]

counts could be readily adjusted simply by varying the path length of the moving filter tape between the two detectors. Similarly, if both alpha and beta-gamma detectors were used, the alpha/beta ratio could be determined, and this information could be used to evaluate the natural radioactivity concentrations, including determining the radon/thoron ratio in air.

In the late 1950s, an interesting constant monitor for particulate radioactivity in air was developed that combined a moving paper filter tape assembly with an impactor (Hoy and Croley 1957). The theory behind this device was that large particles, such as those associated with uranium or plutonium, would be deposited on the filter paper while the smaller particles to which the natural radioactive daughters of radon and thoron attach would follow the air movement and not be collected. Thus, interference from natural background was eliminated. Although this relatively simple device did provide the desired separation of particles, it did not provide an accurate estimate of the hazard from internal emitters, as it did not adequately sample particles in the respirable range.

Initially, radioactive gases were sampled in the field by evacuated flasks, which were opened, usually by means of a stopcock, at the desired sampling location and returned to the laboratory for analysis (figure 18.3). An early field monitor for radioactive gases was described in 1951 and consisted of an evacuated 7.75-l Lucite ionization chamber coated with colloidal graphite (Aquadag) to make it conducting (Block 1951). Air was admitted to the chamber through a stopcock after first passing through a desiccant and a glass wool filter. After the sample was collected, the chamber was directly coupled to a quartz fiber electrometer, charged to zero on the electrometer scale, and the rate of drift timed and compared with a calibration curve made for the specific radionuclide under consideration. The apparatus was particularly applicable to low-energy beta-emitting gases such as tritium and ^{14}C .

Concern over airborne tritium hazards, coupled with increased use and by-product quantities of tritium, led to the development of continuous gas monitors for gaseous low-level beta emitters in the early 1950s (Kanne 1952; Driver 1956). These were largely flow-through ionization chambers, which were soon nicknamed "sniffers." In general, it was difficult to achieve adequate sensitivity with these instruments, unless a very large volume of air was collected, and very sensitive and delicate ammeters were used. Sniffers were also subject to spurious readings from ambient gamma radiation fields, dusts and other aerosols, humidity, and ions in air produced by cigarette smoke or by the passage of the air through the various orifices of the sampling system. Use of filters eliminated most of the problems associated with dusts, aerosols, and externally produced ions, and appropriate design of the sampling lines eliminated the internal ion production problem. Humidity effects were eliminated by a desiccant bed upstream of the sample chamber. Dual chambers—one sealed and one flow-through—were used to provide gamma compensation (Anthony 1959).

The low-sensitivity problem was to some extent solved by using as large a chamber as feasible; for a static device such as an effluent or room monitor, the chamber volume might be as large as 51.5 l, as was used in the Kanne chamber (figure 18.9), which dates back to MED days (Kanne 1952; Hoy 1961). Such large volumes were simply not feasible for portable instruments, not only because of their size but because of the size and weight of the associated air-moving equipment. A more practical chamber size of about 1 l permitted a lower level of detection of several MPCs; later improvements, particularly the advent of solid-state electronics and especially solid-state electrometers about 1960

FIGURE 18.9. A Kanne chamber (see text) installed on an effluent line. The manometer at left was used for flow determination; the piping underneath contains in-line filters for solids. (Photo courtesy of Pacific Northwest Laboratory.)

permitted detection of MPC levels with a high degree of reliability, and reduced the weight and increased the ruggedness of the instrument.

Development of field monitors for tritium and other gaseous radionuclides has been a continuous process, with many novel techniques tried, including concentric chambers (Osborne and Cowper 1966; Talbert 1975), solid scintillation detectors through which the air is passed after prefiltration or other pretreatment (Colmenares et al. 1974), and pulse height discrimination with proportional counters, a technique first developed as early as 1956 (Driver 1956).

Monitoring for plutonium and similar alpha emitters was initially accomplished by standard collection methods for particulates in air followed by alpha counting in the laboratory. Field detection and continuous monitoring of plutonium was revolutionized by the development of semiconductor detectors, which could be used for alpha spectrometry, permitting discrimination against radon daughters or other dust-borne alpha emitters. The first such units appeared about 1960 and permitted the detection of MPC levels of plutonium in workroom air within about eight hours (Phillips and Lindeken 1963). Instruments of this type have been the mainstay of field and in-plant monitoring for plutonium in air for more than two decades. The sensitivity limitation of these instruments is due in part to interference from ^{218}Po , a daughter of radon, which has an alpha energy close to that of ^{239}Pu —5.99 as compared with 5.15 MeV—and thus overlaps with or leaks counts into the plutonium channel. Because of the short half-life of the ^{218}Po , simple holdup can reduce the effect, but more sophisticated techniques such as lifetime analysis, made possible with microprocessor technology, can increase sensitivity by an order of magnitude, permitting detection of MPC levels of ^{239}Pu and other alpha emitters within thirty minutes (Kordas and Phelps 1979).

VI. Radon Monitoring and Working Level Meters

Monitoring of radon and daughters presents special problems and is inherently complicated by the state of equilibrium. In practice, measurements of radon

and daughters can be divided into three categories: (1) radon gas concentration; (2) radon daughter measurements; and (3) working level (WL) measurements.^(a) Radon daughter measurements are usually made with standard sampling instrumentation for airborne dusts followed by direct counting of the untreated sample. Beta counting may be accomplished after allowing the shorter-lived daughters to decay, by a back calculation of activity or concentration present at the time of sampling. Alternatively, alpha counting may be done. More sophisticated techniques involving alpha spectroscopy, determination of alpha/beta ratios or multiple counts at several times after the termination of sampling have also been used, with varying degrees of success. The great difficulty, of course, is the state of equilibrium between radon and its daughters at the time of collection.

As described earlier, early measurements of radon in the field were made on samples collected in evacuated flasks and measured with gold-leaf electroscopes or ionization chambers; calibration was made by comparison with a standard quantity of radon generated from a known amount of radium. Somewhat later, a technique was developed for purifying the radon collected in the flask and counting individual alpha particles, this being done in the laboratory (Curtiss and Davis 1943).

In the mid-1930s, a double ionization chamber method was developed (Evans 1935; Urry and Piggot 1941). One chamber was sealed and served to measure the ambient external radiation. The output from this chamber was used to offset the current from an identical chamber through which the air was passed, the readout of the net current being made with a string electrometer. Sensitivities in the picocurie range were easily obtained, although the operation of the device was somewhat temperamental and required a high degree of skill.

For thoron daughters, a portable ac-operated device was developed in the late 1930s in which the thoron daughters were collected on a brass disk carrying a negative potential of 3000 V (Evans and Goodman 1940). Although air was moved past the collecting disk, the measurement was independent of air flow and was based on counting the deposition of the long-half-lived (10.6-hr) thoron daughter. A proportional counter was also adapted to radon measurement by investigators at MIT (Brown, Elliott, and Evans 1942).

Direct measurement of airborne radon concentrations was improved considerably by the development of scintillation techniques. In the early 1950s, a continuous monitor using a ZnS(Ag) phosphor as the detector was developed by the AEC's New York Operations Office for continuous direct monitoring of airborne radon concentrations (Handloser 1959). Air, filtered to remove the radon daughters, was drawn into a sealed chamber containing a 3-in. diameter photomultiplier tube coated with the scintillation phosphor, the signal from which was fed into a battery-powered rate meter.

The scintillation technique was also adapted to grab sample analysis. In the mid-1950s, the Lucas cell was devised (Lucas 1957). This was simply a 200-ml chamber lined with ZnS(Ag) phosphor, which was exhausted prior to field use. In the field, a stopcock was opened to allow a sample of air to enter the chamber after passing through a filter to remove the dust-borne radon daughters. The scintillations produced by the alpha particles from decay of radon were determined directly with a photomultiplier, which viewed the walls of the

(a) [More in chapter 3.]

Lucas chamber through a clear flat window. This device, which has a sensitivity of about 10 pCi/L, has been widely used as a standard for more than twenty-five years.

An improvement on the Lucas cell was the so-called two-filter method, which utilized a standard air pump to pull air through a metal cylinder about 1 m long (Thomas and LeClare 1970). The cylinder was fitted with a filter at each end. Thus, the radon daughters present in the air being sampled were removed before entering the tube by the first filter, while the filter at the opposite end of the tube removed the daughters generated in the tube as the air was pulled through it. The alpha activity on the exit filter was counted in the field by means of a portable count rate survey meter utilizing a ZnS(Ag) detector. The detection threshold of this method was about an order of magnitude lower than that of the Lucas cell.

Working level measurements^(a) also began in the middle 1950s. The first and still widely used technique was the Kusnetz method, which used essentially standard and relatively simple air sampling instrumentation to collect a sample of dust from a known volume of air (Kusnetz 1956). The technique basically called for the collection of dust from 10 L of air at a flow rate of 2 L/min on a standard paper filter. Direct gross alpha counting of the filter was accomplished for 2 min after a standard delay time of 40 or 90 min; the WL was simply related to the gross alpha activity by a standard constant dependent on the decay time. The Kusnetz method and its many modifications provided an essentially instantaneous or spot sample and required only the use of ordinary air particle sampling and alpha counting equipment; the Kusnetz method was adopted as the American standard method for monitoring in uranium mines in 1973 (ANSI 1973).

The Kusnetz and similar rapid sampling and measurement techniques were lacking in that they were dependent to at least some extent on the degree of equilibrium between radon and its daughters and did not provide either continuous monitoring or a measure of the time integrated exposure to personnel. Moreover, the methods were slow in that a waiting period, commonly 40 min, was required before the analysis could be begun. For the standard Kusnetz method, a minimum of 47 min was required: 5 min to collect the initial sample, a 40-min delay time prior to counting, and a 2-min counting time. With setup time, an hour might typically be required to obtain a single measurement.

The difficulties inherent in the Kusnetz methods spurred development of instant working level meters, continuous monitors, and radon dosimeters by several groups, and over the years, several such devices have been created. Two so-called instant working level meters (IWLM) are relatively recent developments and utilize more complex measurement schemes than the Kusnetz or modified Kusnetz methods. Typically, IWLM devices are built around a surface barrier semiconductor for alpha-particle detection and may use spectroscopic techniques to distinguish between the alphas emitted by ^{218}Po and ^{214}Po . One such early IWLM was developed in 1972 and actually measured the concentrations of individual daughters from which the total alpha energy emitted and hence WL could be calculated (Groer, Evans, and Gordon 1973). This device uses three counting channels, two for alphas using semiconductor barrier detectors and a plastic scintillator for beta. Sampling is accomplished by drawing air through a moving paper tape for a 2-min period, which follows a 1-min

(a) See chapter 3 for details of the development and use of the working level concept.

background count. After sampling, a 2-min count is taken, and the WL is calculated electronically. Only 5 min are required for a measurement.

Only 2 min are required to obtain WL with a surface barrier detector device that measures ^{214}Po and ^{218}Po separately on a filter paper tape through which 1 l of air has been drawn with a hand pump (Schiager 1977). A somewhat earlier device used a surface barrier detector for a gross alpha count during the collection period and for a short period afterward (James and Strong 1973). Yet a different type of IWLM, based on total counts of alpha and beta activity, has also been developed (Shreve, Miller, and Cleveland 1977). All provide WL measurements within 5 min.

Integrating working level monitors actually chronologically preceded the instant working level monitor, with early versions appearing about 1970 (Schiager 1974). These units were based on the use of thermoluminescence dosimeters to integrate the alpha-particle output from dust collected on a filter. Such devices have been successfully used in uranium mines and mills as well as in other applications such as phosphate manufacturing.

Several interesting personnel monitoring devices have evolved in recent years. The radon film badge was invented in the mid-1960s and consisted of a sheet of alpha-sensitive photographic film in a specially designed light-tight holder that permitted entry of radon gas (Geiger 1967). Radon concentrations were determined by counting alpha-particle tracks on the developed film. Other passive personnel dosimeters based on track etch techniques also appeared or were tried about 1970 (Auxier et al. 1971; Lovett 1969; Rock, Lovett, and Nelson 1969), along with a Polaroid device (Bedrosian 1969) and a ZnS-film system (Costa-Ribeiro et al. 1969), thermoluminescence and thermally stimulated exoelectron emission (McCurdy, Schiager, and Flack 1969; Gammage, Kerr, and Huskey 1976), and cellulose nitrate plastic (Alter and Price 1972; Breslin 1977). Recently, active personal radon daughter dosimeters have been developed and appear to show promise (Durkin 1979; Parkinson, Roze, and Shepherd 1981). These devices basically contain a solid-state surface barrier detector and associated electronics including microprocessors to evaluate the counting data, along with a personal air sampler. In practice, air at a low flow rate is drawn through the sampler and deposited on a filter and directly examined by the detector. Sample counting and readout require about three hours, making this device faster than most passive dosimeters, although not as rapid as air-sampling and measurement techniques for determination of the WL. In general, the accuracy and reliability of these devices have been wanting, in particular when they are subjected to harsh mine environments (White 1969).

VII. Surface-Contamination Monitoring

Monitoring surface contamination in the field is vital to the control of radionuclide exposures but is an indirect and generally nonspecific measurement technique. From an internal hazard standpoint, monitoring of alpha surface contamination is of greater importance than monitoring for beta-photon emitters. Almost from the beginning of the MED, surface contamination was monitored in the field by portable survey meters of various types (Morgan 1947, 1950; Parker 1947, 1980) (see figures 18.10 and 18.11). Initially, these early instruments were equipped with gas-filled detectors. As the early state of the art did not permit practical manufacture of a Geiger tube with a window sufficiently thin to admit the short-range alpha particles, thin window unpressurized

FIGURE 18.10. A portable “poppy” for alpha monitoring in the field, dating from before 1950, connected to a battery charger (right). The probe in the foreground was a BF_3 tube, permitting the same portable electronics package to be used for neutrons as well. (Photo courtesy of Pacific Northwest Laboratory.)

FIGURE 18.11. This array of portable monitoring instruments, from early post-Manhattan District days, shows how physical appearance accounted for the rather unusual names in the text. From left to right, the instruments are Bazooka, Portable Poppy, Cart Poppy, Soup Bowl, Cutie Pie, Totem Pole (a later version of the Fish Pole), and, finally, a plain old Geiger counter. The ladies with the Portable Poppy and Geiger counter are both wearing earphones. (Photo courtesy of Pacific Northwest Laboratory.)

ionization chambers and air proportional counters were used. Both types of detectors had disadvantages, including relatively low sensitivity, slow response time, and cantankerous response characteristics. Humid atmospheres would produce erratic response and arcing, particularly in proportional counters, and atmospheric pressure changes could significantly alter sensitivity and calibration factors.

A major problem plaguing the earlier attempts at field measurement of contamination was the general inadequacy and especially the instability of available power supplies. Available power supplies were subject to drift and could not provide the stability of voltage required for trouble-free operation. Thus, an instrument might work well at one site but not at another; an instrument suited to the dry thin air altitude of the Los Alamos mesa (5,000 ft +) might be totally unsatisfactory in the denser more humid air at Berkeley or Oak Ridge. In 1943, this problem was essentially solved by the development of a two-tube balanced circuit by H. L. Overbeck at Oak Ridge, which permitted the production of a power supply suitable to field use. The initial version of this circuit used a pair of 959 vacuum tubes, and the instrument it powered, the "Paint Pail," was relatively insensitive and therefore not useful as an alpha contamination monitor, although it was used for a time for external radiation surveys. Subsequent improvements to the circuit, including the use of a pair of CK 570 AX triodes, made possible the Zeus, a battery-powered ionization chamber survey meter that was used for surface contamination monitoring in the MED. The Zeus circuitry was basically a Wheatstone bridge in which two of the resistors were replaced by the plate resistance of the tubes. The alpha-, beta-, photon-detecting Zeus was subsequently improved by the addition of a feedback circuit, which provided greater sensitivity. This new instrument was named the Zeuto. Typical detection limits were two hundred disintegrations per minute.

At Hanford, the handheld portable air proportional counter was found to be unsatisfactory for in-plant use. In its place, a large ac-powered unit was developed, which featured a standard laboratory binary scaler-rate meter as the readout device in addition to a speaker that sounded clicks or pops to indicate each alpha count (see figures 18.7 and 18.12). Use of

FIGURE 18.12. Exiting an area with the potential for loose alpha contamination; the cart poppy will be used by the monitor at left. Note the radiation warning sign at right, which predates the current three-bladed warning sign adopted in the early 1950s. The sign was white with red lettering and borders. (Photo courtesy of Pacific Northwest Laboratory.)

ac current eliminated many of the problems related to the voltage instability and variability of the dc power supplies available at the time. The device was clearly too large and bulky to be hand carried; the scaler electronics—tube type with heavy iron core high-voltage transformers—weighed well in excess of twenty pounds. Thus, the unit was mounted in a specially designed three-wheeled metal cart with a large handle, allowing it to be moved from room to room or wherever it was needed. This venerable instrument, appropriately named the cart poppy after its popping speaker, served the needs of the Hanford Works for more than three decades. So well thought of was this device that as late as 1969, one operating manager attempted to order identical replacements for his aging original design units, voicing his belief that the instrument simply could not be improved upon. The unavailability of obsolete key components, including vacuum tubes, coupled with potential fabrication costs orders of magnitude greater than modern transistorized replacements, brought the old liner into the solid-state age. The modern replacements were a success, and perhaps thirty years hence identical replacements for them will be ordered by the spiritual descendants of users of the cart poppy.

Despite the drawbacks, the air proportional counter was a mainstay at many laboratories. For many years, Berkeley and Los Alamos favored the air proportional counter, using a handheld portable instrument with a 60-cm² area air proportional counter detector connected to a relatively large vacuum tube electronics package. Total weight of the unit was about two-hundred pounds, leading to the affectionate name of “Pee Wee” for the heavy bulky package. As electronics advances produced improved circuitry and in particular voltage regulators, portable air proportional counters of various types flourished. Another major advance occurred about 1955 with the practical production and application of wire with a diameter of 0.0005 in., which allowed better collection efficiency and more uniform fields in the detector, minimizing probe microphonics and other environmental effects.

At Hanford, the favored portable alpha monitor was the scintillation “poppy,” made possible by the development of the scintillation counter and especially photomultiplier tube advances during and shortly after World War II (Curran and Baker 1944; Kallman 1949; Coltman and Marshall 1947; Morton 1949) (see figure 18.8). The poppy converted the light flashes from a ZnS(Ag) scintillator into audible “pops,” one pop for each light flash. Initially, contamination levels were determined by counting the number of pops emitted by the instrument during a specified time period, which could be as short as 10 or 15 sec for relatively high levels and extended to a minute or two for very low levels. A proportional counter version of the poppy, developed at Oak Ridge (Borkowski and Marsh 1945), also was used for a time but could not compete effectively with the convenience and advantages of the alpha scintillator, which included stability, good rejection of beta and photon radiations, and typically greater sensitivity. Subsequently, a count rate meter was added, providing visible indication of the level of activity, but, at least at Hanford, the meterless instrument remained in use well into the 1960s. Scintillation detectors offered several advantages over gas-filled detectors, including greater sensitivity and much faster response time. They were not so dependent on highly stable power supplies and were unaffected by changes of humidity or pressure. They also produced a large signal, which could take advantage of relatively simple circuitry. They did, however, have a major drawback in that the photomultiplier tube was light sensitive and had to be kept in total darkness. Even a tiny pinhole in the

ZnS sheet covering the photocathode would admit enough light to produce high count rates and perhaps even damage the photomultiplier or at least render the instrument out of service for a period of hours.

The difficulties with the portable alpha instruments using gas-filled and scintillation detectors led to the development of a portable gas flow proportional counter by the Eberline Instrument Company in the late 1950s. This instrument was unaffected by environmental variables such as temperature and pressure and was equipped with a small pressurized bottle of counting gas. It was ideally suited to outdoor use where temperature and humidity changes might occur and was unaffected by pressure changes, since it maintained a constant flow of counting gas. Therein lay its drawbacks; the gas bottle ran dry after a few hours of operation and needed to be replaced; this was relatively expensive. In addition, the instrument was larger than the comparable scintillation or air proportional models because of the gas bottle "piggybacked" under the electronics package. Nonetheless, the instrument gained considerable acceptance. Gas flow could be checked visually in the field or elsewhere by igniting the gas streaming from the tiny outlet port of the detector. This made for a practical if not dramatic visual demonstration that the detector was operational and also permitted the gas flow to be adjusted appropriately by observing the size of the flame. It also was quite an attention-getter in operation; many a worker has done a quick double take at a health physics technician casually surveying a laboratory with a probe with a tiny blue flame emanating from its upper surface. Some more enterprising technicians, with a flair for the theatrical, would pretend to be searching for lost alpha particles that were visible only in blue light, or they would nonchalantly use the flame to light cigarettes when demonstrating the instrument outside of radiation areas. To date, there is no recorded instance of any accidental fires from these theatrics.

A key need in the early days of the MED was the detection of contamination on bench tops and similar flat surfaces, and for this purpose a box-like portable instrument with the detector opening on the bottom was built. This early instrument, named Juno, used a large ionization chamber as a detector. The chamber was equipped with a window thin enough to permit the entry of alpha particles and thus could be used as an alpha-contamination monitor, although it was relatively insensitive. Sliding shields—one plastic and one aluminum—could be used to cover the chamber window, permitting the instrument to be used as a beta-photon contamination monitor, or as a survey meter for external beta-photon radiation fields. The Juno was joined by the Samson (figure 18.13), an instrument of similar design and built for exclusive use as an alpha survey monitor;

FIGURE 18.13. The Samson portable alpha meter. The chamber opening was underneath the instrument, making it convenient for monitoring surfaces. Note calibration graphs taped to the instrument. (Photo courtesy of Pacific Northwest Laboratory.)

its name may have been derived from the acronym SAM for standard alpha meter and the word son, as a second generation or "son" of the Juno. The Juno was among the first of the wartime instruments made commercially, and it proved to be remarkably venerable, still existent in the 1980s with modern MOS-FET (metal oxide silicon field effect transistor) and integrated circuitry in a physical configuration essentially identical to that of the first models.

Hand and shoe monitors, shoe monitors, and hand monitors also were developed in the MED and continue in use today, conceptually identical but far more sophisticated electronically (figure 18.14A, B). Portal monitors were also devised as a passive means of evaluating whether a person exiting a radiation zone

FIGURE 18.14A. (Above) An early portable hand monitor. Readout was provided by a binary scaler shown to the right of the detector; timer and register are mounted under the shelf supporting the scaler.

FIGURE 18.14B. (Left) The unit in use. Note saddle shoes, popular in 1940s, worn by user.

(Photos courtesy of R. L. Kathren and Pacific Northwest Laboratory.)

might be carrying radioactive contamination. The portal monitor consists of a door-sized opening framed by a number of detectors. As the individual passes through the opening, the contamination on (or in some cases in) the person will be detected. Typically, the individual would be required to pause in the portal for a time—perhaps as much as 90 sec, although from 10 to 30 sec was more common—to provide reasonable detection capability. Portals were (and are) typically narrow, to reduce the source-to-detector distance and improve detection capability. The more sophisticated models were designed to identify the detector that had the greatest count rate, which crudely localized the contamination. Other monitors, such as portal monitors and the walk-over monitor designed at the Savannah River Laboratory (Splichal 1972), were physically very large but achieved greater sensitivity and positive control in that personnel had to pass through the device in order to exit the facility. Floor monitors made their appearance in the 1940s, and basically were an adaptation of portable instruments to large-scale area monitoring. The Pee Wee was one of the many portable instruments adapted to this purpose.

The early portable instruments were tagged with a variety of often colorful, frequently obscure, and sometimes bizarre names (figure 18.11). To some extent, they reflected the security needs of the times, coupled with the perhaps wry sense of humor shown by the designers and users of the devices. Thus, to the Pee Wee already discussed can be added the Pluto, Juno, Sniffy, Samson, Chang and Eng, Paint Pail, Fish Pole, Bazooka, Giraffe, Zuto, Zeus, and, of course, the health physics mainstay, the Cutie Pie. Not all of these were useful for internal emitters; the Chang and Eng, for example, was a neutron survey meter with two identical appearing cylindrical chambers connected by a metal bar. The perhaps bizarre, but certainly fitting, name was derived from the famous Siamese twins of the Barnum and Bailey sideshows that excited an earlier generation.

The origins of many of these names are obscure; according to one source (Kathren 1975), the name Cutie Pie, now generically used to describe portable ionization chamber instruments, may have been derived from the fact that the response was a function of the charge (symbolized by physicists in mathematical expression as " Q ") and the geometry which was " 2π ." Hence, "Cutie Pie." Another story holds that the name was derived from the exclamation of a health physicist, who reportedly said "Isn't that a little cutie pie?" when he was shown the first prototype by the development engineers.

Important information regarding radionuclide contamination could often be inferred from measurements of external radiation fields, or sometimes inadvertently by instruments designed to measure external fields. An example of the latter is the film badge, which was typically worn by radiation workers in the MED and became, in fact, the ubiquitous symbol of the radiation worker. Contamination in the form of radioactive particles would sometimes settle or adhere to the badge, and when the enclosed film was developed, would appear as dark spots. This crude incidental autoradiography of contamination particles was quickly recognized by film badge technicians and utilized by operational health physicists to identify and control potential intakes of radioactivity. In the jargon, such films (and perhaps the wearers) were referred to as having measles because of the mottled appearance of a contaminated film, and the health physicist following up on a contaminated film incident was thus "investigating a case of measles."

Film badges were tried as early as the MED days for perimeter monitoring but, because of their inherent low sensitivity and susceptibility to environmental

damage, found little application. Both radiophotoluminescent and thermoluminescent dosimeters have been used with considerable success for external ambient measurements around nuclear facilities since the 1960s. One of the primary purposes of such dosimeters is to measure the external radiation fields in the environs of operating nuclear power plants, including the external radiations associated with the radionuclides and radiokryptons. The latter are primarily beta emitters, and dosimeters with a suitable "open window" and shielded area are necessary to gain quantitative information on the time-integrated release or concentration in terms of MPC-h of the noble gases.

Despite their great limitations, measurements of external photon fields have been used by operational health physicists since the earliest days of the MED to gain information on environmental contamination levels and the potential for internal exposure through intake of radionuclides. Geiger counters and scintillation chambers, because of their high sensitivity and fast response time, were ordinarily used for such purposes, although ionization chambers have been developed specifically for this purpose. Among the earliest applications of such instruments to protection from possible internal exposure were floor monitors, in which an array of several G-M tubes was suspended a few inches above the floor in a wheeled shielded housing. The readout ratemeter, electronics package, and operating controls were conveniently located at about waist height, enabling the operator to push the entire device along hallways and through various work areas, detecting contamination lying on the floor. Such instruments initially were designed and built by the various AEC sites, but by the mid-1950s, several commercial instruments of this type became available. Geiger-Müller and scintillation detectors were also mounted on vehicle bumpers and used for road or environmental area surveys. Portable Geiger counters and scintillators used in the field provided useful, albeit crude and primarily inferential, measurements of the hazard potential from internal radioactivity. They did, however, enjoy considerable vogue in uranium prospecting work, particularly during the 1950s.

A major limitation of both G-M counters and scintillators is photon energy dependence, which makes accurate measurements of environmental radiation levels difficult at best. This problem can be overcome by suitable response flattening filters, but these tend to reduce sensitivity and eliminate the all-important beta response. Although ionization chamber instruments have the disadvantage of poor sensitivity, one way of increasing sensitivity is with a pressurized ion chamber, thereby increasing the number of gas molecules in a given volume available for interaction. This requires special circuitry and led to the development of the Neher-White ionization chamber, originally developed in the 1940s by H. V. Neher and L. H. White. This device utilized an ionization chamber filled with pure argon at a pressure of 10 atm. With a chamber volume of only 50 cc, it was possible to measure over a range of six or seven decades. Despite their numerous limitations, including poor beta sensitivity and poor linearity of response, commercial portable survey meters featuring Neher-White circuitry and pressurized ionization chambers were popular for three decades and found wide application in fallout contamination monitoring associated with atmospheric weapons testing.

Cylindrical aluminum air ionization chambers with a volume of 40 l were used primarily at the Hanford site for a number of years to monitor ambient photon fields and to detect environmental contamination (Rising 1960). The ionization current was read out directly by a portable battery-powered

electrometer mounted atop the large volume chamber, which, because of its size and appearance was nicknamed the "milk can" by the calibration technicians and radiation monitors who used them in the field. The tube-type electrometers initially used were temperamental and not very rugged, and the units were upgraded with solid-state electrometers when these became available in the late 1950s.

More germane to internal emitter problems is the Pluto, a portable monitor for plutonium or other alpha-emitting surface contamination developed during the MED days. The instrument was named after Mickey Mouse's dog, Pluto, a very popular cartoon figure during World War II. The name, however, upset General Groves on security grounds because of its similarity to the then-secret element-plutonium. He thus decreed that the name should not be used, and for a time the instrument was renamed "Sandy" after Little Orphan Annie's dog in another popular cartoon strip of the time. Officially, the instrument was designated "Snoops," but, General Groves notwithstanding, the name Pluto stuck, and, along with the Sniffy, an appropriately named air sampling device, the Pluto was one of two health instruments named in the Smyth Report published immediately after the atomic bombings of Japan (Smyth 1945).

An interesting and highly effective device for monitoring plutonium contamination in the field under adverse environmental conditions was developed as a result of a military aircraft crash in 1964 near Palomares, Spain, involving nuclear weapons. Known by its acronym FIDLER (Field Instrument for Detection of Low Energy Radiation), this device used a thin scintillation detector and a two-channel pulse height analyzer set for 17 keV and 60 keV (the plutonium and ^{241}Am photons); it is capable of detecting plutonium contamination levels of a few hundred nanocuries per cubic meter over rugged uneven terrain (Tinney, Koch, and Schmidt 1969).

Portable battery-powered spectrometers for field application made their appearance about 1960, largely made possible by the advent of the transistor. One of the earliest commercial units was a single channel analyzer made in the configuration and size of a handheld survey meter by the Eberline Instrument Company. A later version of this unit featured two channels, and subsequent models made by Eberline and other manufacturers had special features such as hard-wired detection capability of the 364-keV photon associated with ^{131}I and scanning capability.

Although some water monitoring was done in the MED, the method used was simply immersion of detectors of various types into the liquid, useful only for fairly high concentrations of beta-photon emitters. Somewhat more sophisticated monitors were developed shortly after the war, using several thin side wall G-M counters to enhance sensitivity (Hursh, Zizzo, and Dahl 1951). Isotopic measurements of specific radionuclides in water were made in the field by ordinary gamma spectroscopy techniques. A combined alpha and beta-photon water monitor was made commercially as early as 1952, having both G-M and ZnS(Tl) detectors (AEC 1952). Systems have also been made for continuous measurement of tritium in water using a flow diversion-mixing technique and liquid scintillation counting.

VIII. In-Vivo Counting

In its simplest form, in-vivo counting could be accomplished by using a G-M survey meter to detect iodine in the thyroid if the activity levels were sufficiently

high (figure 18.15). Direct field measurement of internal emitters in vivo was accomplished by use of whole-body counters, which were made relatively lightweight and transportable and, hence, suitable for field use. Early whole-body counters were simply large shielded rooms; one such unit, developed at Brookhaven National Laboratory, weighed twenty-one tons and was transported by ship for use in fallout studies of the Marshallese (Cohn et al. 1963). Shadow-shield whole-body counters were pioneered at the Hanford Laboratories (Palmer and Roesch 1965) and made into portable truck-mounted units (Swanberg 1963; Brady and Swanberg 1965). A similar mobile whole-body counter was also developed in Sweden (Van Döbeln 1965). Although the sensitivity of these devices was initially not nearly as good as could be achieved in the laboratory using large shielded rooms with graded shields, for many applications, particularly for detection of fission products, these devices are more than adequate. In a typical unit, subjects would lie on their back on a cot or bed which was moved underneath a large NaI(Tl) crystal shielded overhead and on the sides by lead. Thus, a traverse of the body was obtained. The shadow-shield detector had a background as low as the large iron room systems, and weighed only five tons (Palmer and Roesch 1965). Thus, it could be loaded into a truck or even onto aircraft to make in-vivo field measurements and was used in studies of fallout in school children in the Hanford area and in Eskimos and Laplanders in the Arctic; and in the Marshall Islands (see chapter 12, which includes a photograph of one such unit). The modern successor to the original Hanford design is now commonly used at nuclear power plants to routinely monitor workers for internal exposure to fission products. The much more ponderous and sensitive non-portable (laboratory) versions of in-vivo counters are described in chapter 17. The transportable units described here are simply modifications of the larger laboratory versions.

FIGURE 18.15. Field measurement of radioiodine contamination in the thyroid during the 1940s. (Photo courtesy of Pacific Northwest Laboratory.)

Portable survey instruments were also used to detect possible internal contamination from radionuclides, particularly the radioiodines, which are relatively rapidly taken up and localized in the thyroid (figure 18.15). Routine contamination surveys, at least on one occasion, are known to have detected

accidental internal contamination from radioiodines.^(a) More recent and modern techniques include a "quickie" type counter, which combines features of the portal monitor, in-vivo counter, and sophisticated computer-based multi-channel analyzer to provide an indication of internal gamma-emitting nuclides within a few seconds, at levels considerably below the maximum permissible body burden.

IX. Summary and Commentary^(b)

As in all branches of science, progress in the field of radioactivity was linked closely to advances in instrumentation and methodology. For measurement of contamination with radionuclides, either in-plant or in the environment, it was necessary to develop light-weight and rugged instruments. The developments aimed primarily at plant and site monitoring and, later, general field use are reviewed briefly in this chapter. The principles are no different from those applied to laboratory instruments and described in chapter 17.

Portable instruments were used in the field quite early by the cosmic-ray physicists. Also, the needs for monitoring medical installations that were using radium or x-ray machines stimulated the development of so-called R-meters, film badges, and the like.

During the Manhattan Project days these basic instruments were adapted to the conditions and different energies in the plants and to measuring environmental contamination on- and offsite. Much had to be done to develop instruments that could measure alpha-particle contamination with reasonable accuracy and still be rugged and portable. Details, including the colorful code names given to many of these field and monitoring instruments, are in the chapter along with pictures of some. They also are listed in the capsule chronology.

There were, of course, some new or almost new developments in the earlier years that were of special importance to these applications. Among these were low-voltage Geiger-Müller tubes, the development of special materials and quenching gases suited to high radiation fields, and thinner and stronger windows for alpha counters.

(a) On a Friday afternoon in the spring of 1964, an alert health physicist at the Nevada Test Site correctly interpreted the results of a personnel contamination survey made with portable G-M survey meters by technicians on several individuals who were exiting from tunnelling re-entry following an underground nuclear detonation. The affected personnel all showed measurable closed window radiation levels localized in the vicinity of the neck. They had been wearing respiratory protection suitable for particulates but not radioiodines. The affected individuals were flown to Livermore, where they were met at the airport and escorted to the whole-body counter at Donner Laboratory by a Livermore health physicist and technician. The counting (by Donner personnel), which lasted until nearly midnight that evening and through the next day as well, revealed a mixture of five radioiodines (mass numbers 131 through 135) in the thyroids of the four affected individuals. The most seriously exposed had an estimated thyroid dose approaching a kilorad. This rather bizarre incident underscored the importance of in-vivo counting as an operational health physics tool and was an important factor in justification of the first whole-body counter at Livermore; it also sparked a data sheet in *Nucleonics* on the relative activity of the radioiodines as a function of time after fission.

(b) [This summary was written by J. N. Stannard and was not seen in advance by the chapter's author.]

Much of the field and monitoring methodology involved air sampling and, to a lesser degree, sampling of water and biota. Measurements in-vivo were less common until the later years. For air sampling, the techniques of industrial hygiene were adapted to obtaining samples suitable for measurements of radioactivity. Gradually these became continuous monitors, and they became important, not only for record-keeping, but to provide warnings of any breaks in the containment systems. Similarly, continuous monitors could be set up in the environment to transmit information on the presence of, and any changes in, outside contamination. The adaptation of air-sampling procedures to measurements of radon and its progeny in air is described (see also chapter 3).

The methods used for the collection of fallout from nuclear weapons tests are not described here since they were reviewed briefly in chapter 12. The radiation measuring instruments applied to the fallout once collected varied from in-situ measurements with field instruments such as those described here to transportation of the samples to the laboratory for preparation and analysis by laboratory instruments. For more than very rough measurements, radionuclides such as plutonium and the actinides required elaborate radiochemical separations prior to measurement. These important procedures have had to be given short shrift in this book, but they can be found in the cited literature.

Field measurements of external beta or beta-gamma radiation from fallout were routinely done by methods related to the in-plant and environmental monitoring procedures of the nuclear energy industry, with some special modifications. Special mention should be made of a fairly recent development—the FIDLER, a scintillation detector that can conveniently provide waist-height measurements of plutonium surface contamination. It can even be mounted in an aircraft and used to survey ground contamination. While precision is not equal to good in-situ measurements on the ground, and certainly not to laboratory measurements, this device can survey fairly large areas in a short time. Thus, areas of high activity can be spotted, and the ground crews can be directed to them.

For many years, portable radiation detection instruments were kept available in communities for use in case of a civil defense emergency. It should be clear from this chapter that the shelf-life of such instruments is short enough to require regular maintenance. Also, they cannot be trusted in untrained hands. Perhaps we can look forward to the future development of field instruments that are always at the ready and ridiculously simple to operate. With solid-state technology, thermoluminescence, and related developments, current field instruments are very light, small, and rugged, in sharp contrast to those available in the 1930s and 1940s.

Preface to Section VI

Therapy and Nuclear Medicine

The two chapters in this section are as close to clinical medicine and associated pharmacology as we will get in this compendium.

At several points in earlier chapters, e.g., radium (chapter 1), actinides (chapter 7), experience with fallout (chapter 12), we alluded to or briefly described approaches to the therapeutic removal of deposited radionuclides from the body, or prevention of their absorption. Actually, the subject was in the investigators' minds throughout the research and industrial experiences recounted. Since a body or tissue burden of a radionuclide cannot be turned off like an x-ray machine or other source of external radiation, the only recourses are to prevent or delay absorption or hasten elimination. The same problems concerned many in the field of chemical toxicology, especially the deposition and removal of heavy metals such as lead. Pharmacologists were busy trying methods and synthesizing chemicals that would, they hoped, complex with heavy metals and bring about the desired effects. This began even before World War II. Much effort was also devoted to developing antagonists for war gases. These activities were picked up by those interested in possible therapeutic removal of radionuclides. Small, but active, research groups pressed the investigations, and, before long, clinical trials were being started. Thus, there was both active research into the compounds and their effects in animals, as well as pressures to check out the results in humans. The possible need, should an emergency arise, was strong motivation for clinicians attached to the organizations handling radionuclides in quantity. As a result, this is one area where the conventional pharmacologist-toxicologists and representatives of the internal emitter establishment worked quite closely.

Chapter 19 reviews the early experimental approaches to therapeutic procedures, the development of chelators and chelation therapy, the active experimental programs, and briefly, the experience in humans. Because the work was in many respects more strongly developed in European laboratories than in the United States, the chapter has more review of work done abroad than many chapters in this book. What it does not say is that chelation therapy has, despite the problems noted in the chapter, become a more or less standard form of potential treatment. Nearly every installation where human beings handle reasonably large quantities of radionuclides has the means for chelation therapy in stand-by form in its medical department.

In chapter 5, we saw the beginnings of the use of radioisotopes for diagnosis and therapy that were later called nuclear medicine. In chapter 6, we saw that therapeutic uses were on the minds of investigators at Berkeley when they were deflected by more urgent problems. Even during the war years, these possibilities were not forgotten; indeed, some progress was made as the accelerators became more powerful and the nuclear reactor began to supply radionuclides in quantity. At the end of the war, many clinicians who had been sequestered by war work were anxious to make use of the potentials revealed, and nuclear medicine took off on an expansion that has hardly slowed at all ever since. Chapter 20 reviews the aspects of nuclear medicine with direct bearing on the theme of this book—the health effects of radionuclides.

For obvious reasons, the detailed clinical aspects of nuclear medicine procedures are far too extensive for more than a glimpse in chapter 20. Imaging and other diagnostic aspects had to be given short shrift. Yet, there is enough to convey the fundamental nature of the operations. Uses in therapy receive more attention, for here we are dealing with a direct health effect of the radionuclide. Also, much emphasis is placed upon a central theme of nuclear medicine, viz., the extraction of maximum diagnostic information with minimal radiation dose to the patient, or maximum therapeutic effect in the target tissue or organ, with minimal effects on other nontarget tissues or organs.

Dosimetry of internal emitters receives formal discussion in chapter 20. Obviously, the principles of such dosimetry have had to be appreciated at many earlier points in our discussions. However, it seemed wise to put off formal presentation until both the “conventional” system and the one developed by the Medical Internal Radiation Dose Committee (MIRD) of the Society for Nuclear Medicine could be discussed together. (The reader was warned of this delay in the general preface.)

Chapter 20 ends with some gratuitous remarks on possible extensions of current trends in therapy that may or may not develop in the future. Nuclear medicine is such a rapidly developing field that one is emboldened to make prophecies!

It might be thought that financial support and manpower for nuclear medicine would be far less associated with the activities of government than many other areas we have reviewed. This is now true. Yet, in the formative years, the field got much of its impetus and some of its support from the agencies we have become familiar with in earlier sections. Even organized medicine, strong as it now is, could not or would not have supported the construction and operation of the accelerators that produced the radionuclides that gave nuclear medicine its start. This is even more true of the extensive program for distribution of radionuclides from nuclear reactors for cancer research and therapy and other biomedical uses begun under the Atoms-for-Peace program, probably its most durable contribution to posterity.

OUTLINE

THERAPEUTIC PROCEDURES FOR DEPOSITED RADIONUCLIDES

Capsule Chronology	1579
Overview	1585
I. Introduction	1587
II. Early Approaches	1588
A. Radium	1588
B. Work in the Manhattan Engineer District	1589
C. Other Work During World War II	1591
III. The Early Postwar Years—Complexing Agents Take Over	1592
A. Citrate and Other Normal Physiological Entities	1592
B. Metal Displacement—Colloid Formation—Zirconium	1593
C. Chelation and Chelating Agents	1595
D. Review of Reviews	1598
IV. Experimental Work with Animals in the Postwar Era	1600
A. Zirconium	1600
B. British Anti-Lewisite	1604
C. The Main-Line Chelators	1607
1. The Actinide (Transuranic) Elements	1607
a. Mobilization	1607
b. Reduction of Biological Effects	1617
c. Removal of Inhaled Actinides	1620
2. Use of “Main-Line” Chelators for Removal of Other Elements	1620
D. Modifications of the Main-Line Chelators and Substitutes	1625
1. LICAMs	1625
2. Lipophilic Compounds	1626
3. Adjunctive and Mixed-Ligand Therapy	1629
a. Adjunctive Therapy	1629
b. Mixed-Ligand Therapy	1632
E. Nonchelating Therapy	1633
F. Therapy for Inhaled Radionuclides	1638
1. Physiological Approaches	1639
2. Complexing Agents	1640
3. Lung Lavage	1644
V. Experience in Man	1647
A. Experimental Studies	1647
B. Accidental Exposures—Clinical Management	1652
1. Overview	1652
2. Specifics	1655
a. Zirconium	1655
b. Early Trials in Man with EDTA-DTPA	1657

3. Crescendo of Experience	1660
4. Conclusions Regarding Clinical Experiences	1669
VI. Pharmacology and Toxicology of the Main-Line Chelators	1670
A. Pharmacology (Pharmacokinetics, Pharmacodynamics)	1671
B. Toxicology of the Main-Line Chelators	1677
1. Kidney Damage	1677
2. Hypocalcemia	1678
3. Acute Lethality	1678
4. Relative Toxicity of Zn-DTPA	1679
5. Effects on the Embryo and Fetus	1680
6. Pulmonary Toxicology	1682
7. Toxicity of Puchel	1684
8. Miscellaneous Toxicological Findings	1684
9. Approval of Zn-DTPA by the Food and Drug Administration ...	1685
VII. Summary and Commentary	1685
References	1687

Capsule Chronology

- 1926 Deleading procedures proposed and tried, mostly by manipulation of calcium metabolism (Aub, Evans, et al., Massachusetts General Hospital and MIT).^(a)
- 1927 Viosterol and parathyroid extract considered for deleading.
- 1929 Parathyroid hormone used for therapy of radium poisoning (Flinn and Sedlin, John Hopkins).
- 1931 Viosterol used for above (Flinn).
- 1935 Dietary calcium changes tried for removal of radium (Craver and Schlundt).
- 1938 Deleading treatments outlined above applied to patients and animals with body burdens of radium (Aub et al., Massachusetts General Hospital and MIT).
- 1942 First suggestion of use of a complexing agent for decorporation of heavy metals (Kety).
- 1945 Importance of complexing emphasized in all work with deposited radionuclides (especially Neuman et al. at Rochester; Schubert, Met Lab).

Development of British anti-lewisite (BAL) for treatment of chemical warfare agent effects, e.g., lewisite; leads to ideas for decorporation of heavy metals (Peters and others, United Kingdom).
- 1946 Berkeley works hard on factors influencing absorption and retention—cathartics, low- and high-calcium diets, etc. Tried for strontium, yttrium, cesium, and plutonium.

Chicago work on effects of sodium citrate and related complexers on excretion of plutonium in animals (Paintér).
- 1947 Idea of metal displacement advanced by Schubert (Chicago). Uses zirconium. Also considerable expansion of work on sodium citrate.
- 1948 BAL does not work for uranium (Neuman and Allen at Rochester).

Toxicity of zirconium reported to be low in rats (McClinton and Schubert, Argonne).
- 1949 Zirconium administration tried for plutonium and yttrium in animals (Schubert, White, and colleagues, Argonne).

Hursh shows increased removal of polonium in rats by BAL (Rochester). Also 1952.
- 1950 First test of EDTA for removal of a radionuclide, viz., plutonium (Foreman, Berkeley). Also general reports on chelation work at Berkeley (Foreman).

BAL only moderately successful for thorium.
- 1950s Hanford begins work on removal of inhaled radionuclides; continues for many years (Tombropoulos and Bair).

(a) For abbreviations and acronyms, see Appendix D.

- 1950s** Use of complexers and chelators for treatment of wounds at Hanford reviewed.
- Chelation chemistry advances rapidly, and chelators are tried in many laboratories.
- Various physiological variables tried.
- Experimental work begins on uses of chelating agents in humans.
- 1951** Report of radiostrontium metabolism and decontamination in man (Laszlo and Spencer at New York).
- Trial of BAL for removal of ^{32}P and ^{90}Sr ; not effective (Kisilefski et al., Argonne).
- 1952** Hursh demonstrates changes in tissue distribution of polonium after BAL (Rochester).
- First description of toxicity of chelators.
- 1953** Detailed work on nature and importance of citrate complexes with uranium (Feldman and Neuman at Rochester).
- Early Los Alamos work on chelating agents (Foreman).
- Work on zirconium begins at Hanford (Temple, Wager, Joffe, and Thompson).
- 1953-1965** Several reviews by Foreman on pharmacology of chelators.
- 1954** Sodium and calcium-EDTA compared and latter preferred (Foreman, Los Alamos).
- Early joint Hanford-Los Alamos reports on chelation trials in man (Foreman, Fuqua, and Norwood).
- Trials of BAL for removal of plutonium not successful (Kawin and Copp, Berkeley).
- Hursh demonstrates that BAL reduces toxicity of polonium in rats.
- 1955** EDTA kept ready at Hanford for possible use in accident cases (Norwood).
- Zirconium used in human contamination case at Hanford (Norwood).
- Mid-1950s** Trials of DTPA and EDTA in man begin at Hanford and Los Alamos.
- Becoming evident that zirconium action is a carrier effect, not a metal displacement, and is limited to circulating radionuclides.
- Idea advanced that zinc removal may underlie toxicity of chelators (Schroeder).
- 1956** Americium exposure case at Berkeley treated with Ca-EDTA (Dobson).
- Ca-EDTA tried at Argonne in ^{227}Th wound case.
- Rosenthal edits AEC general report on therapy of radionuclide poisoning (Argonne).
- Ionophoresis tried for skin decontamination (Michon, France).
- Berkeley group tries zirconium for removal of yttrium (Copp and Kawin).

- 1956** NRDL tries zirconium (Cohn et al.).
MacDonald (UCLA) declares medical armamentarium for radiostrontium removal is lamentable.
Kidney damage reported in a few patients receiving DTPA (Foreman and Lushbaugh, Los Alamos).
- 1957** Zirconium used on two cases in the United Kingdom. Side effect of serious labyrinthitis in both cases causes much concern and essentially cuts off further use of zirconium therapy in humans.
Ultrasonic methods tried at Hanford (Neef and Ballou).
- 1960** Book by Seven and Johnson on metal binding in medicine is a landmark for the field.
Reports of nephrotoxicity of some chelators. Schroeder reviews pharmacology of chelators.
- 1960s** Extensive animal work with EDTA, DTPA, DFOA, and other chelators done for removal of transuranics in animals (Taylor, U.K.; Fried, Schubert, Rosenthal, Lindenbaum, Argonne; Smith and colleagues, Battelle; Belyaev, USSR; Seidel, Volf, FRG; Lloyd et al., Utah; Cohen et al., NYU).
Potentially lower toxicity of Zn-DTPA indicated by Norwood (Hanford).
Miscellaneous substances tried for removal of radiostrontium. Reviewed by Nelson (United Kingdom) in 1963.
Much work by Spencer and colleagues on metabolism of tracer levels of many radionuclides in man. Chelated forms compared to ionic forms.
Hypocalcemia with chelators reviewed (Seven).
Spencer reviews experimental work on radiostrontium removal in man.
- 1961** Diuresis and diuretics tried for removal of radiocesium.
Chelating agents tried for removal of thorium (Fried and Schubert, Argonne).
- 1962** Several human cases at Hanford described at symposium on Biology of the Transuranic Elements. DTPA substituted for EDTA. Decorporation as effective in man as in animals.
IAEA meeting on diagnosis and treatment of radioactive poisoning.
Work on removal of inhaled radionuclides at Hanford reported (Tombropoulos and Bair).
Catsch addresses general principles of chemistry and pharmacology of chelators.
- 1962 et seq.** Search continues for effective oral chelating agent (Ballou, Hanford).
- 1963** French experience described for DTPA in wounds (Lafuma).
Use of chelators in the Marshall Islands from 1955 on, described by Cohn (Brookhaven).
Volf on treatment of radiostrontium uptake in man.

- 1963 Prophylactic and therapeutic measures described in Hanford symposium on radioiodine.
Several agents tried for ruthenium removal (Catsch et al.).
Plurionics tried at Hanford; other surface-active agents, also extensive cadre of parasympathetic drugs.
- 1964 Schubert reviews pharmacology of chelators.
Iron complexers tried (Keberle).
Chelators do only moderately well for removal of inhaled radionuclides (Hanford).
Lovelace Laboratory enters studies of removal of radionuclides from lung.
Idea proposed of adding inert agents to increase lung elimination rates (LaBelle, Rochester-Jefferson). Effect small.
- 1965 Early Rocky Flats reports.
- 1966 Review of Rocky Flats contamination cases, mostly wounds, and the therapies used (Piltingsrud).
European work on Prussian blue in man.
- 1968 Reports of attempts to change gut absorption in man; extend over many years.
Alginates tried for same purpose in animals (Stara and colleagues, USPHS).
Schulte and Whipple (Los Alamos) question use of chelators.
- 1968-1969 Lung lavage tested for removal of plutonium from animal lungs (Sanders, PNL; Pflieger, Lovelace).
- 1969 Methods for reducing gut absorption reviewed by Bair and Smith (PNL).
Zymosan tried for increasing phagocytic removal of ^{137}Cs in fused clay (Thomas et al., Lovelace).
Dosage regimens for chelation compared (Rosenthal et al., Argonne).
- 1970 Work on promethium in man (Palmer and Nelson, PNL).
- 1970-1974 Work at Fontenay-aux-Roses on treatment of intramuscularly injected transuranium elements (Nénot, Morin, et al.).
- 1970s Much work in Europe on relative toxicity of Zn-DTPA versus Ca-EDTA.
Series of reports from Lovelace of use of pulmonary lavage (Muggenburg et al.).
Much work at Utah on toxicity of chelators to embryo and fetus.
Case of americium contamination of long standing (began in 1963) found in Albany, New York. First published findings in 1972. Father and son exposed. Therapy with DTPA continued periodically through 1975. Measurements continue (Cohen, Wrenn, and colleagues, NYU) for several years.
- 1972 Pulmonary lavage used on human case contaminated with plutonium (McClellan et al., Lovelace).

- 1972** Small nebulizers developed for giving chelators as aerosols (Smith, PNL; Jolly, Savannah River).
Lovelace reports on intravenous DTPA for removal of inhaled materials (Pfleger and colleagues).
Ca-DTPA causes a transient inhibition of DNA synthesis; Zn-DTPA does not (Taylor et al., United Kingdom).
- 1973** Review of Hanford-Battelle inhalation and wound cases from 1946 through 1971 (Parker).
Review of DTPA effects on removal of trivalent actinides (Durbin, Berkeley).
Reduced absorption of radiostrontium with sodium alginate reported (Borisov, USSR).
Ferri-ferrocyanide tried for removal of radiorubidium (Richmond, Los Alamos).
Glucan \pm DTPA tried for removal of plutonium from liver (Rosenthal et al., Argonne).
Work begins at Battelle on pulmonary toxicity of chelators (Smith, Ballou, and colleagues).
- 1974** Lethality of large doses of Ca-EDTA attributed to removal of zinc.
- Mid-1970s** Utah group enters chelation therapy field in earnest (Calder, Lloyd, Mays). Zn-DTPA considered more effective than Ca-EDTA for long-term use and less toxic.
- 1975** Review of therapy of sixteen human cases, primarily wounds, by Dolphin (United Kingdom).
French work on pulmonary lavage. Able to lavage both lungs at single sitting (Nolibé).
- 1976** Catsch shows that margin of safety is narrower for continually maintained blood levels of Ca-DTPA than for single or spaced doses.
Utah reports on Ca-DTPA and Zn-DTPA for removal of americium.
Cohen (NYU) compares americium metabolism and effects of therapy in man to that in baboons.
- 1977** Some measurements made of reduction of effects in animals treated by pulmonary lavage (Muggenburg, Lovelace).
- 1978** Fifty-four human cases summarized by Volf (FRG).
Comprehensive review, also by Volf, published by WHO-IAEA.
Mixed ligand therapy described (Schubert). Subsequently proven ineffective.
- 1979** Lavage favored as most effective method for removing inhaled long-lived radionuclides (Muggenburg, Lovelace).
Seventh edition of Albert's book on selective toxicity reviews chemistry of chelators and chelation and broad applications of these agents.

- 1979 Argonne work on chelation of plutonium in liver (Bhattacharyya et al.).
The saga of the Richland americium case begins (Heid et al., PNL).
- 1980 New specific sequestering agents for actinides (Durbin, Berkeley).
NCRP report on management of persons accidentally contaminated
with radionuclides.
Twelve-year decorporation course reported in case of americium con-
tamination in Pittsburgh (Rosen, Wald, et al.).
- 1981 More on chelation research at Utah, including report of brain damage
in beagle fetus (Mays et al.).
Actinide-specific sequestering agents described in review (Raymond
and Smith, PNL).
- 1982 Summary of findings and effects of therapy in Richland americium case
published as special issue of *Health Physics*. Toxicity of Puchel reported
(Smith et al., U.K.).

Chapter 19

Therapeutic Procedures for Deposited Radionuclides

Overview

In the decade of the 1930s, concern for possible means of therapeutic removal of radium generated efforts that have gone on ever since, to either prevent deposition in tissues or remove deposits of radionuclides from the tissues of the body. The efforts never reached the stage of major programs such as those developed for pulmonary radiotoxicology or the understanding of the basic behavior and effects of deposited radionuclides. Nevertheless, some of the principal laboratories in the United States have had programs in almost continuous operation, and some individuals have devoted their scientific careers to the subject. Also, major installations with potential for serious contaminating incidents have been duty-bound to have facilities, personnel, and procedures at the ready in case of need. This chapter considers much of the research done to provide clinicians with useful methods for the therapy of contamination of humans with radionuclides.

Useful methods were indeed devised that clearly lengthened the life span and reduced suffering in cases, fortunately few, of significant contamination. The work also contributed in many ways to our understanding of how radionuclides are handled by higher organisms and to the possible roles of trace metals in normal physiological processes.

This chapter and the one to follow (on nuclear medicine) involve more overt interaction between laboratory research and clinical medicine than most of the earlier chapters in this book. They do not enter fully into recommendations for clinical practice, since this is in the domain of the clinical judgment of the cognizant medical team. They do, however, give easy access to most of the compendia containing specific recommendations for medical management.

Also in contrast to earlier chapters, in this chapter there is an almost equal mix of work done in the United States and in European laboratories. This is partly because the major developments were after World War II, except for some of the fundamental concepts of complexing, which developed in U.S.

laboratories near the end of the Manhattan District days. Active programs developed in the United Kingdom, West Germany, France, and the Soviet Union simultaneously with those in the United States. There was very active liaison among the groups, and each new idea got tested thoroughly on both sides of the Atlantic. For this reason, and because the U.S. effort was not the massive one characteristic of some other programs, work in several laboratories here and overseas is discussed simultaneously as appropriate to the subject matter at hand. We have had to eschew the careful chronology of contributions, laboratory by laboratory.

There is first a rapid review of the early attempts to mobilize radium by manipulation of calcium metabolism through diet and the use of drugs. The extensions of these attempts to radionuclides such as strontium that, like radium, behave as calcium does are woven into the picture essentially chronologically. There is also some exposition of the many efforts to influence metal metabolism by modification of normal physiological processes. This includes metal displacement and the use of colloid formers such as zirconium.

The bulk of our attention, however, is directed toward the development and role of various complexing agents and processes. It starts with the use of sodium citrate, the role of the war-time-developed British anti-lewisite (BAL), and then comes down hard on the chelators of the polyamino-polycarboxylic-acid type such as EDTA, DTPA, and their many derivatives. Included are some of the relatively recently developed agents such as the LICAMs, Puchel, etc.

In order to define the agents more or less uncluttered by details of the biomedical experimental work, there is a separate section (section III) devoted to a capsulized exposition of the rapid growth of complexing, especially by chelating agents. This is followed by details of the experimental work with animals, much of it in tabular form to allow the most extensive coverage in the least space (section IV). There is a separate section on treatment of inhaled radionuclides.

The section on experience in humans is divided into two parts: one concerned with experimental work at the tracer level; the other a review of some human contamination incidents in the United States that have come to therapy. While relatively few in number, these have been very thoroughly studied and documented. The findings are taken up in some detail herein.

An important feature in the use of these therapeutic modalities, particularly the chelating agents, has been the need to understand their intrinsic pharmacological behavior and their manifestations of toxicity. Some of this is inextricable from discussion of the experimental findings themselves. Yet, it seemed to require highlighting as a separate section (see Pharmacology and Toxicology of the Main-Line Chelators), particularly since the internal emitter establishment invested considerable effort in the pharmacology and toxicology of chelating agents.

There is no doubt that the preparations for therapy of deposited radionuclides have been worthwhile. Several lives have been saved—or at least materially extended. In this regard, the work merges with the much more common problem of therapy of the heavy metals such as lead, mercury, etc. Indeed, the internal emitter establishment benefited greatly by the development of agents by industry and in universities primarily for application to these more widespread problems and vice versa. In addition, the work has yielded insight into many basic aspects of how the body handles radioisotopes. These aspects could not be emphasized in the chapter to the extent they deserve, but they are hinted at wherever possible.

I. Introduction

In view of the high toxicity and long-term effects of many radionuclides when deposited in the body, it is not surprising that considerable effort has been expended to devise ways to prevent their uptake or deposition, to hasten their elimination, or to ameliorate their effects. This has applied especially to the long-lived elements that deposit in bone.

Prevention of uptake and hastening of elimination have received by far the most attention. Attempts to ameliorate the effects of deposited radionuclides by means other than prevention of uptake or deposition or by hastening of removal have little pertinence except for conventional medical and surgical procedures. It is true that toward the end of World War II and in the earlier postwar years, a large program was mounted, especially in laboratories associated with the Armed Forces, to attempt to reduce the effectiveness of absorbed doses from ionizing radiation. Almost all of the work utilized radiation sources external to the body and was applied primarily to single acute doses. A few substances were moderately effective. These have been catalogued as "radioprotective agents." However, they are generally effective only if present essentially at the time of irradiation. The protection afforded is very short-lived and would clearly be of even less use for internally deposited radionuclides since the radiation dose is much more prolonged than the action of the protective agent, and repeated doses of the protective agent are not practical.^(a)

Ideas pertinent to possible therapy of radium poisoning were investigated in the 1930s along with the crescendo of work on radium in animals and humans. We will recap the results briefly in the following section.

With the development of biomedical work on the fission products and the actinides during World War II, some attention was given to applying the procedures generated for radium to these new elements.

By far the largest effort went into the development of and experimental trials with various agents that could form complexes with the pertinent metals and thus, it was hoped, prevent their fixation in tissue or mobilize them for excretion if they had already been deposited. In this area, the workers with radioisotopes had much aid from the whole field of metal toxicology and the clinical experiences with common heavy metal poisons such as lead and mercury. Furthermore, the synthetic chemists had much more than the stimulus of scattered exposures to radionuclides to motivate them toward the development of new agents. The basic chemistry of these complexing agents received very concentrated attention and has been reviewed extensively.

The net result has been development of a few fairly standardized therapeutic procedures that are kept available in case of need. The agents themselves have sometimes turned out to be toxic in their own right, and frequently the desired therapeutic level cannot be attained or maintained because of the undesirable side effects of the therapeutic agent.

The laboratories and investigators concerned with the work on radioisotopes were largely those we have already identified with the internal emitter programs. Most of the major efforts in the United States were supported by the Atomic Energy Commission (AEC) and its successor agencies. Notable additions,

(a) The literature is so replete with reports of the work on radioprotective agents that no attempt will be made to review it here. Any good review of radiobiology will tell the story.

particularly on the clinical side, came from pharmacologists and physicians faced with major problems of heavy-metal poisoning. There have been major efforts also in other countries, especially England, France, Germany, and the Soviet Union.

Since the generation of therapeutic procedures for deposited radionuclides has received attention in relatively manageable proportions and has been concentrated in a relatively few institutions, reviews are both numerous and comprehensive.

II. Early Approaches

A. Radium

In the chapter on radium (primarily ^{226}Ra) we saw that ideas for "deleading" patients were proposed as early as 1926 by Dr. Joseph Aub and his many associates (e.g., Robley Evans, D. Hunter, R. McLean) at the Massachusetts General Hospital (MGH) and Massachusetts Institute of Technology (MIT). On the theory that radium would be at least as much like calcium as lead is, an approach to therapy was investigated through manipulation of calcium content of the diet and of calcium metabolism (e.g., by adding vitamin D, parathyroid hormone, etc.). A few patients and some animals with radium burdens were given this "deleading" type of treatment in 1937-1938. As indicated and referenced in chapter 1, it was possible by these procedures to increase radium elimination rates in the urine. However, the effect on total body burden of radium was disappointingly small. In the patients, the radium burden was usually of long standing, and the amounts accessible to removal without untoward perturbations of calcium metabolism were small.

Further work revealed that lead tagged with radiolead (^{210}Pb), and radium as well, deposit preferentially in trabecular bone, while the cortex remains initially relatively free of radioactivity. Gradually, the amount in cortex increases, presumably by migration from the trabeculae. Later work in Germany confirmed the presence of this pattern, this time using mesothorium. The deposit in cortex was in all cases much less mobile than that in trabecular bone. As the metal deposits in the apatite crystals, it becomes less and less available to mobilization. Additional work indicated that there are areas of greater and lesser mobility, even in cortical bone. At a meeting held at Argonne National Laboratory (ANL) in 1955, on therapy of radioelement poisoning, the field was reviewed in depth.

Dr. Aub gave an introductory address that elegantly reviewed the story of the classic contributions made to the field by these early studies on lead, radium, and calcium. A few of his remarks are reproduced below:

I have tried to give some idea of the work which a good many of us, mostly Robley Evans and myself, have done in the study of metal deposition in bone. After the metal gets deposited, then the problem is what to do about it, and that is the subject of this symposium.

There are several very discouraging things about therapy. If patients arrive for treatment early, the radioactive substances are in the trabeculae, an area from which they can be liberated. Many years later, as in the patients Dr. Evans and I have studied, radium is mostly in an area over which one has little control. Then it is mostly in the cortex; much less is in the trabeculae. The methods which we used then for decalcifying did increase the excretion rate of the radium about ten-fold. This is interesting but you are dealing with minutiae because the daily excretion rate is such a small fraction of a percent of the total metal stored.

One thing is very discouraging—the kidney is very ineffective in excreting radium. The amount of radium in the blood, at any given time, was the amount of radium which was excreted in the urine in 24 hours, so that the kidney did not excrete most of the radium which was presented to it. The kidney is, therefore, not efficient in excreting radium that is in low concentrations in the blood.

(Aub 1955)

Nevertheless, a fairly standard regimen was kept available (see section V).

B. Work in the Manhattan Engineer District

Obviously, the groups at Berkeley, in the Metallurgical Laboratory at Chicago, and at Rochester were aware of the earlier work with radium, lead, and other heavy metals. The pressure of finding out about the behavior of the new elements in the fission product and actinide series and the problems of uranium in large quantities left little time for exploration of means for therapeutic removal. Nevertheless, some work was done that is worthy of our review now.

The first mention of the possible importance of complexes to the behavior of fission products, plutonium, and uranium is found in a Metallurgical Laboratory memorandum from Jack Schubert to Waldo E. Cohn (Schubert 1945). As the title indicates, the thrust was as much toward methods for determining their composition and dissociation constants as toward their use in therapy.

At the date of Schubert's early work, quantitative data on the complex-forming properties of many substances depended on the classic frog heart method used in physiology and pharmacology. This was applied to the dissociation of calcium complexes since the beat rate of the frog's heart is a function of calcium ion concentration. The method had many limitations. Schubert proposed the use of ion-exchange methods, particularly for citrate complexes. He proposed an immediate program to investigate the citrate and tartrate complexes of strontium and of at least one rare earth.

Meanwhile, at Rochester, complexes of uranium with bicarbonate, protein, and citrate, and their biological importance, were being investigated and reported in the classified literature. This is reviewed briefly in chapter 2 and in the immediate postwar literature cited therein.

In 1946, the Berkeley group devoted a large part of one detailed report on strontium, yttrium, cesium, and plutonium to factors affecting absorption and retention (Copp, Greenberg, and Hamilton 1946). In the first chapter, they found, using adult female rats, that large cathartic doses of magnesium sulfate, sodium phosphate, sodium bicarbonate, etc., had little effect on absorption of radiostrontium (isotope not stated) from the gut. Only tricalcium-disodium phosphate, administered ten minutes after the radiostrontium, reduced absorption measurably. This agent is classed as an absorbent.

A high calcium diet also reduced gut absorption, even when given as discontinuous supplements. On a low calcium diet, absorption was elevated. By varying the periods on the diet, it was determined that the absorption depends more on the body's need for calcium than on the concentration in the gut at the time of administration of the radiostrontium. There was little effect of adding stable carrier strontium on the uptake of radiostrontium. Active growth had a significant effect as did also a prolonged period on a diet low in calcium. From these results, the authors suggested supplementing the normal human diet with dairy products or medicinal calcium to deter strontium uptake if such is anticipated. This was based on the premise that the human diet is usually low in calcium.

In the second chapter (same authors), they turn from oral to injected strontium. Parathyroid hormone, irradiated ergosterol, and a high citrate diet were used in addition to manipulations of calcium intake. Again, the only significant variables were age (rate of growth) and the state of calcium nutrition.

A third chapter (Copp, Chace, and Hamilton, same report) turns to the uptake of plutonium, yttrium, and cerium, in addition to strontium. There was again a marked effect of age and dietary calcium on strontium deposition in the skeleton. But there was no significant effect on plutonium, yttrium, or cerium isotopes.

The fourth chapter (Copp, Van Middlesworth, Cuthbertsen, Chace, and Hamilton) considers the effects of various treatments on *elimination* of deposited strontium, yttrium, cesium, and plutonium. They used parathyroid hormone, ammonium chloride, and sodium citrate; also a regimen consisting of a low-calcium diet, supplemented by ammonium chloride and parathyroid hormone, which is labeled as "the standard regimen commonly employed in treating chronic radium poisoning."

The procedures did increase the elimination of strontium somewhat, but not enough to materially reduce the body burden. They had no effect on the other elements.

A fifth chapter (Van Middlesworth, Copp, and Hamilton) describes uptake of radiostrontium, radioyttrium, and plutonium in healing fractures. Again, strontium was the most mobile, i.e., it reached the highest concentration in urine, although its peak occurred at about eight days, while those for plutonium and yttrium occurred somewhat earlier.

Severe phosphorus deficiency was the subject of the sixth chapter (Copp, Chace, and Hamilton). There was a fourfold reduction in retention of radiostrontium, but no significant effect on retention of plutonium, yttrium, or cerium. The phosphorus deficiency was severe and hardly a practical therapeutic modality.

Autoradiography of the bones, studied in the final chapter (Axelrod, Copp, and Hamilton) showed large areas of organic matrix free of bone salts. Plutonium, yttrium or cerium deposited in these. Strontium, by contrast, deposited only in the presence of bone salts. This work, along with earlier metabolic work, led to the conclusion that only strontium follows calcium metabolically. The other elements, basically of the rare-earth type, have metabolisms unrelated to calcium. This important conclusion has remained valid for decades and is still true, except that it is no longer accepted that plutonium et al. combine only with the osteoid matrix of bone.^(a) On this basis, therapy by manipulating calcium homeostasis would not be expected to do much except for strontium.

A final result of the autoradiographic study was the demonstration of overlayering of deposited radioisotopes by newly formed nonradioactive bone with consequent shielding of bone-marrow cells from alpha particles. This bears, of course, on the difficulty of therapeutic removal after a bone-seeking isotope has been in place for a considerable period.

The Chicago work on therapy of radionuclide deposition during the Manhattan Engineer District (MED) days examined the effects of sodium citrate

(a) Some of these same experiments and conclusions were published in the open literature in 1947, e.g., Copp, Axelrod, and Hamilton (1947). Others are quoted in chapter 7.

and of added hypertonic saline on excretion of plutonium. In the large report on clinical physiology of dogs injected with plutonium, which we examined in chapter 7 (Painter et al. 1946), the effect of these agents was described in one dog. The citrate was given to complex the plutonium following the ideas enunciated by Schubert, and the hypertonic saline was given to produce a diuresis. On the fifty-third day after receiving plutonium, the dog was fed 1.5-g sodium citrate capsules twice daily for ten days and then was given 0.7% sodium chloride twice daily by intravenous injection for seven days. The average urinary excretion rose from 0.005% of the injected dose per day to about 0.0065% of dose per day toward the end of the period of citrate treatment. It remained at about this level during the period when hypertonic saline was added. It quickly fell back to or even below the rate in the original control period on cessation of the treatment. A second period on hypertonic saline brought about a second rise, but only back to the 0.005%-per-day level.

This was hardly a dramatic result. Nevertheless, the authors felt that the approximately one-third increase in excretion rate was worthy of follow-up in cases where the plutonium had been present for a shorter period and was thus less "buried." Also, they speculated that citrate administrations twice daily would not maintain a high blood level of citrate for more than a small part of the day. They recommended more frequent citrate administrations.

These ideas were indeed followed out in post-MED work, but it is not clear whether or not these suggestions directly generated the later work. It is clear that the MED work added the idea of complexing of heavy metals to the systems based on diet and manipulation of calcium metabolism seen in the treatment of radium and lead poisoning.

C. Other Work During World War II

There was much activity in the Chemical Warfare Services of the United States and Britain that later bore fruit for the therapy of many types of poisonings. Both British and American laboratories were busy developing antidotes for the chemical warfare agents. Some of these agents contained metals like arsenic, and one of the antidotes was British anti-lewisite (BAL), which turned out to have dramatic effects against the arsenical, lewisite (Peters, Stocken, and Thompson 1945). We will discuss BAL and its uses more in sections III and IV.

In a more peaceful realm were the results of work by Seymour Kety on the use of citrate^(a) as a complexing agent for lead (Kety 1942). This appears to have been the *first suggestion*^(b) of the use of complexing as a *general* tool for decorporation of heavy metals in vivo.

There was, of course, much related activity in pharmacology and therapeutics during the war years. Radiotoxicology and heavy metal toxicology have shared the action for many decades. The early postwar reviews show the extent of this sharing.

(a) While the suggestion was unique and the arguments from stability constants persuading, citrate did not turn out to be a very effective agent in clinical cases of lead poisoning.

(b) Schubert's suggestion, made three years later and already cited, appears to be the first application of the idea to radioisotopes.

III. The Early Postwar Years—Complexing Agents Take Over

In the postwar years, the bulk of new contributions to the possible therapy of deposited radionuclides concern the development and use of complexing agents. It was a great expansion of the ideas generated during the war. Since the chemical character and biochemical actions of these agents must be understood before we can profitably discuss the experimental work, this section is devoted to a brief review of those subjects. Much more detail can be found in reviews to be cited in the section entitled "Review of Reviews."

A. Citrate and Other Normal Physiological Entities

Sodium citrate can form relatively strong complexes with metal ions, as was demonstrated during the years of World War II. At the second annual conference of the Utah Project (see chapter 8), Schubert (1954) expanded upon the ideas presented in the MED literature. He pointed to the rapid metabolism of citrate in the body as a probable reason for disappointing and spotty results. The complex with the metal does not exist for long unless new citrate is available. Destruction of the complex will release the metal again. In some cases, the effect may even be a negative one in that the complex may have carried the metal into tissue, e.g., bone. Therefore, methods such as continuous intravenous drip of citrate were suggested and even tried. The greater efficacy of other agents discouraged wide application of this clumsy method.

Meanwhile, a different approach was suggested, also by Schubert. Let the body make additional complexing agents *in vivo*! For example, relatively enormous amounts of citrate are produced daily in the course of normal tissue metabolism. It is usually broken down rapidly. However, sodium fluoroacetate, another product of research on chemical warfare agents that saw considerable postwar use as a pesticide, inhibits the reaction that breaks down citrate. Schubert describes tenfold to one hundredfold increases in citric acid content of soft tissues like spleen and kidney in animals given sublethal doses of fluoroacetate. He reports also reduction of lead burden when present in these animals by a factor of three in twenty-four hours. He apparently did not try the idea on radioisotope removal. Similar, but less marked effects can be obtained by blocking citrate formation by other means.

Schubert also had some ideas to help explain lack of efficiency *in vivo* when the *in-vitro* chemistry (e.g., stability constants) of the complexing agent and metal in question predicted success. These revolve around accessibility. In many cases, complexing agents do not enter the intracellular sites of deposition and thus remove only the amounts of radioisotope circulating in the blood, or in extracellular spaces. This was illustrated with citrate and lead. The disproportionately small removal of lead by citrate seems to occur when the lead is within the red blood cells. If the amounts of lead are sufficiently high so that the red cells are saturated and there are appreciable amounts in plasma, then the lead removed by citrate is relatively much greater. We will see presently that the question of accessibility is of great importance with all of the complexing agents.

Meanwhile, the ability of citrate to form soluble complexes with many heavy metals and radioisotopes thereof was utilized throughout the AEC, and in pharmacology and toxicology laboratories everywhere, to permit administration of the metals in a soluble form or to solubilize them for other purposes.

In many laboratories, detailed physicochemical work was done on the nature of the citrate complexes. At Rochester, for example, Feldman and Neuman (1953) worked with the uranyl-citrate system and did spectrophotometric studies.

Other naturally formed complexing agents have been tried. Among these are succinate, pyrophosphate, and bicarbonate. These are, in general, too labile to have much therapeutic potential. However, the work that developed our knowledge of them had great importance in suggesting how the metals are normally carried in vivo. It appears that calcium, barium, strontium, and probably radium are held in bone as complex ions. Any mobilization will depend upon both accessibility and the relation of the stability constants of the bone complex and the exogenous complex.

B. Metal Displacement—Colloid Formation—Zirconium

Work done at Chicago near the end of the war and reported in 1947 introduced a different idea from complex formation per se. This too was the brain child of Jack Schubert (Schubert 1947). He suggested, particularly for removal of plutonium, the administration of large amounts of metals with high valence, with metabolism similar to plutonium, and with very low toxicity. On the basis of mass action and ion exchange reactions, it was postulated that the administered metal would displace the plutonium (hence the term "metal displacement therapy").

In 1947, Schubert showed encouraging preliminary results in rats by administration of zirconium.^(a) Urinary excretion of plutonium was increased far above control levels and well above that resulting from doses of sodium citrate. The results are shown in table 19.1, taken from the Schubert paper.

A second injection of zirconium produced a second rise in plutonium excretion. There was no effect at any time on the quantity of plutonium excreted in the feces. Tissue analyses showed a significant reduction of the skeletal content of plutonium, as well as of that in liver. However, the amounts in muscle and kidneys were higher in the treated animals.

Schubert reported also on the effect of zirconium on plutonium excretion in a dog. He found the rise in excretion to be proportional to the amount of zirconium injected. It continued for about three weeks.

Rats treated five weeks after injection of plutonium showed a roughly tenfold increase in urinary excretion of plutonium after treatment with zirconium (compared to the fifteenfold increase when zirconium was given earlier after plutonium administration). In these animals, the liver content was reduced *but not that of bone*.

Zirconium treatment had only a negligible effect on excretion of strontium or its concentration in liver or bone. This led to the postulate that only those elements laid down in the uncalcified organic matrix of bone and in the endosteum and periosteum would be amenable to zirconium therapy.

In both the cited work and in a separate report (McClinton and Schubert 1948), the toxicity of zirconium, tested in rats, was found to be very low, and no long-term effects were noted. This finding, coupled with its apparent effectiveness, led to much experimental work with zirconium, including therapeutic

(a) He also tried cerium and lanthanum, all in their stable forms, but zirconium showed the most promise.

TABLE 19.1. Effect of Zirconium and Sodium Citrate Treatment on the Urinary Excretion of Plutonium in Rats*

(Data expressed as average per cent of injected dose of plutonium excreted each day)					
Days elapsed following Pu Injection	Pu Control	Treatment			
		Zirconium (100 mg on 2nd hr. and 3rd day after Pu injection)	Zirconium (50 mg. on 2nd and 24th hr. after Pu injection)	Sodium citrate (4 ml. of 10% sol. on 2nd hr. and 3rd day after Pu injection)	Sodium citrate (2 ml. of 10% sol. on 2nd and 24th hr. after Pu injection)
0-1	0.75	8.2	5.1	3.2	3.1
1-2	.051	.12	.66	.07	.68
2-3	.027	.032	.060	.037	.041
3-4	.041	.60	.078	.19	.041
4-5	.045	.022	.060	.016	.023
5-7	.022	.07	.058	.011	.018
7-10	.021	.064	.083	.020	.017
10-12	.024	.060	.059	.021	.010
12-14	.016	.064	.053	.026	.022
Total Pu excreted in urine for 14-day period. . .	1.1	9.6	6.5	3.7	4.0

* The rats (200-gram females) received 1.1 mg. of Pu/kg.

trials in humans. We will review the latter in section V. Suffice it to say here that the promise was fulfilled in part, but toxicity problems were much greater than anticipated.

Later work showed considerable variation in the effectiveness of zirconium citrate for different radioelements. Relations to the formation of hydroxides with colloidal characteristics, especially the formation of small aggregates in the blood stream at physiological pH, were more consistent than the stability of the complexes. This led to consideration of agents like zirconium as "colloidal scavenging agents" rather than as simple metal displacers. The removal process thus might involve not only metal displacement but adsorption onto the colloidal aggregates. Under proper conditions, these aggregates were still small enough to pass through the kidney glomerulus into urine. A further reason for this postulate was that the final distribution was that of zirconium, not that of plutonium.

Whether ion exchange, coprecipitation, or colloid formation is the chief mechanism cannot be stated with confidence, but most workers at the time leaned toward the latter. Probably both occur, but in different proportions for different elements and conditions.

C. Chelation and Chelating Agents

The processes of complex formation and colloidal adsorption discussed in parts A and B are closely related to and lead into the processes and agents formally called "chelation" and "chelating agents." The term is derived from the Greek word *khēle* for claw. When two or more ligands in a molecule form coordinate bonds *simultaneously* with a metal atom, the chemical structure gives the appearance of a claw holding the metal atom. Such molecules are called chelating agents. The more "talons" there are in the claw the more stable the chelate, up to a point. The official terminology is to call compounds "unidentate," "bidentate," "polydentate," or "multidentate," etc., according to the number of ligands holding the metal. Classic groups for such binding are anions of oxo acids (e.g., $R-C=O$), neutral molecules which can donate a nitrogen atom (e.g., $R-NH_2$), etc. Thiol (i.e., $-SH$) groups also coordinate well with metal ions. However, the affinities are quite different among the ligands binding the metal.^(a)

The first chelation-type compound to receive general attention was the already-cited BAL, structurally a relatively simple compound.^(b) It is shown in figure 19.1A and as a metal complex in figure 19.1B. It forms coordination compounds with many metals.

FIGURE 19.1A. Structure of British anti-lewisite.

FIGURE 19.1B. British anti-lewisite as a metal complex.

As stated above, the work was begun by Rudolph Peters and colleagues (1945) in England. It has turned out that BAL is really effective for only a few metals but works very well when it does work.

Effects of BAL on radioisotope deposition and removal were studied primarily at ANL and the University of Rochester. We will examine details in the next section. While there were a few instances of notable success with BAL, the cadre

(a) The difference between ordinary electrovalent binding and covalent binding, the process involved with these compounds, is that the organic portion of the molecule contributes both valences. This contrasts to ordinary binding where an anion contributes an electron to a deficient cation to form a stable union. In complexing or coordinate binding, the metal frequently loses its original properties as an ion. (Actually this happens to some extent with citrate binding, but the characteristic "claw" structure is not so prominent.) The result of this loss of original properties as a metal ion is sometimes advantageous; sometimes it poses problems.

(b) The chemical name is 2,3 dimercaptopropanol, sometimes shortened to dimercaprol.

was small, and soon other substances were investigated as chelating agents. Thus, the polyamino-polycarboxylic acid chelating agents came on the scene. A tabulation of the structure, abbreviations, and full chemical names for some of these is given in table 19.2.

TABLE 19.2. Polyaminocarboxylic Acids Employed in Therapeutic Removal of Heavy Metals

Abbreviation	Name	Structural Formula
EDTA	Ethylenediaminetetraacetic acid	$\begin{array}{c} \text{HOOCCH}_2 \quad \text{CH}_2\text{COOH} \\ \diagdown \quad \diagup \\ \text{NCH}_2\text{CH}_2\text{N} \\ \diagup \quad \diagdown \\ \text{HOOCCH}_2 \quad \text{CH}_2\text{COOH} \end{array}$
DTPA	Diethylenetriaminepentaacetic acid	$\begin{array}{c} \text{HOOCCH}_2 \quad \text{CH}_2\text{COOH} \\ \diagdown \quad \diagup \\ \text{N-CH}_2\text{-CH}_2\text{-N-CH}_2\text{-CH}_2\text{-N} \\ \diagup \quad \diagdown \quad \diagup \quad \diagdown \\ \text{HOOCCH}_2 \quad \text{CH}_2\text{COOH} \quad \text{CH}_2\text{COOH} \end{array}$
TTHA	Triethylenetetraminehexaacetic acid	$\begin{array}{c} \text{HOOCCH}_2 \quad \text{CH}_2\text{COOH} \\ \diagdown \quad \diagup \\ \text{NCH}_2\text{CH}_2\text{-N-CH}_2\text{CH}_2\text{-N-CH}_2\text{CH}_2\text{-N} \\ \diagup \quad \diagdown \quad \diagup \quad \diagdown \quad \diagup \quad \diagdown \\ \text{HOOCCH}_2 \quad \text{CH}_2\text{COOH} \quad \text{CH}_2\text{COOH} \quad \text{CH}_2\text{COOH} \end{array}$
BAETA	2,2'-bis-[di(carboxymethyl)amino]diethyl ether	$\begin{array}{c} \text{HOOCCH}_2 \quad \text{CH}_2\text{COOH} \\ \diagdown \quad \diagup \\ \text{N-CH}_2\text{CH}_2\text{-O-CH}_2\text{CH}_2\text{-N} \\ \diagup \quad \diagdown \\ \text{HOOCCH}_2 \quad \text{CH}_2\text{COOH} \end{array}$

Many of these compounds were synthesized for other purposes, primarily for increasing solubility of other substances. Indeed, the first member of the group, EDTA, is the old detergent, "Versine" or "Versene," the terminology depending upon geography.

A flurry of activity took place in the early 1950s around EDTA. In fact, it appears that EDTA was first tested at Berkeley for the removal of plutonium from animals (Foreman 1950), and the work toward complexing stable heavy metals followed. Berkeley, Chicago, Hanford, Los Alamos, and the Naval Radiological Defense Laboratory were particularly involved. In Europe, there was much activity: e.g., in the United Kingdom, Dame Janet Vaughan at Oxford University and Professor David Taylor at the Royal Cancer Hospital; in West Germany, in the laboratory of Professor Alexander Catsch at the Karlsruhe Institute; in France at J. C. Lafuma's laboratory at Fontenay-aux-Roses, and also at laboratories in the Soviet Union.

This work involved both experiments with animals and therapeutic applications in man as well as the development of agents such as DTPA, etc., cited in table 19.2.

Since all of these compounds form stable complexes with calcium, great care is needed to prevent undue removal of body calcium and the serious consequences thereof. One of the chief problems has been striking a suitable balance between complexing of the unwanted metal and withdrawal of undesirable amounts of calcium from the blood and body stores.^(a) To guard against this,

(a) Removal of other essential metals is also a potential problem but of less significance (see the next section).

calcium is now always given along with the chelating agents. In figure 19.2A, the formula for sodium EDTA is repeated, along with a postulated reaction in which calcium enters the chelate and sodium is released. The binding of other metals is presumed to occur in the same way as shown for calcium. Another possible structure of the calcium complex is shown in figure 19.2B. Both formulae are from a paper given by Harry Foreman at the Second Annual Utah Conference (see chapter 8) where the possibilities for the polyamino-polycarboxylic acids were first expanded upon (Foreman 1954, 1955).

FIGURE 19.2A. (Left) Possible structural formula of EDTA and its complex with calcium. (Redrawn from Foreman 1954. Reprinted with permission of the University of Utah Press, Salt Lake City, Utah, copyright 1954.)

FIGURE 19.2B. (Right) Alternative structure for the calcium chelate with EDTA. (Redrawn from Foreman 1954. Reprinted with permission of the University of Utah Press, Salt Lake City, Utah, copyright 1954.)

Obviously, a large amount of good chemistry was needed to measure dissociation constants (or stability constants) of the many chelating agents with the many metals of importance, both endogenous and exogenous. The in-vitro work was done well, and predictions of general validity could be made regarding the potential efficacy of a given agent toward a given metal. However, as the experimental work progressed, there were many surprises, and many predictions were only partially fulfilled. In the stable metal area, there were so many surprises that the workers began to feel that our knowledge of how heavy metals act was really very deficient. In the radioisotope area, there were surprises too, but since the effects were from a common cause, ionizing radiation, usually uncomplicated by the biochemical effects of the metal ion itself, the dilemmas were actually less profound.

Before we proceed to examine the experimental work, another set of chelating agents needs introduction. These are agents that have special affinity for

iron. There is a family of such agents. One of them is desferrioxamine (DFOA), which is produced microbiologically and has enjoyed some success in treatment of iron poisoning and iron storage diseases. Structurally it looks grossly like the members of the EDTA group, but the complex with iron is entirely through oxygen linkages (Keberle 1964, cited by Vaughan 1973). The structure is shown in figure 19.3A and B. Since plutonium chemistry and iron chemistry have many parallels, this agent and some other iron chelators have been tried experimentally to remove plutonium and other actinides (Taylor 1967; Durbin et al. 1980). This agent seems to be ineffective for actinides other than plutonium.

FIGURE 19.3A. Iron chelator structure—desferrioxamine chemistry. (Redrawn from Keberle 1964 via Vaughan 1973. Reprinted with permission of Springer-Verlag, New York, copyright 1964.)

FIGURE 19.3B. Iron chelator structure—ferrioxamine B. (Redrawn from Keberle 1964 via Vaughan 1973. Reprinted with permission of Springer-Verlag, New York, copyright 1964.)

A host of other agents have been tried for therapy of deposited radionuclides. In fact, it sometimes appears that there are few things that have *not* been tried for therapeutic removal of metals and of their radioisotopes. However, these do not routinely fall into the category of complexing agents per se and will be discussed when relevant to the development of the experimental work.

D. Review of Reviews^(a)

Because of the close relationship between all of chelation chemistry, heavy metal toxicology, and many important clinical problems, it may be useful to list here a few of the most pertinent reviews that will give background for our discussion of the experiments in the radioisotope field. Some are mostly chemical in orientation, others provide biomedical findings parallel to those we have introduced and will discuss further in sections IV and V. A short annotation accompanies some of the reviews.

(a) The venerable Chauncy Leake, one of the founders of the *Annual Review of Pharmacology*, capped off each volume with a "Review of the Reviews" in that volume. I have borrowed his title for this section.

The reviews^(a) are:

1. Reviews by Schubert and Foreman in *Second Annual Conference on Plutonium, Radium and Mesothorium*. University of Utah Radiobiology Laboratory. C. N. Stover, ed., 1954.
2. "Chelating Agents." by Harry Foreman. A reprint of the chapter from the Utah symposium; in *Industrial Medicine and Surgery* 24, (7), 1955.
3. *Therapy of Radioelement Poisoning*. AEC Report ANL-5584, 1956. A symposium was held at ANL in 1955 and edited by Marcia White Rosenthal. Contains early clinical as well as experimental work on a variety of agents. The appendices contain summary tables of work to date of writing.
4. *Metal Binding in Medicine*. Book edited by M. J. Seven and L. A. Johnson (1960). A very broad spectrum of chapters on all aspects of the subject from basic chemistry and pharmacology to specific disease entities. From a symposium held at Hahneman Medical College, Philadelphia.
5. *Diagnosis and Treatment of Radioactive Poisoning*. International Atomic Energy Agency, Vienna, 1962. Proceedings of a meeting sponsored jointly by WHO and IAEA. Contains sections on radium, strontium, other fission products, plutonium and other transuranium elements, and treatment plans. International flavor.
6. "Therapeutic Removal of Transuranic Elements." Section in Hanford symposium, *Biology of the Transuranic Elements*, 1962. *Health Physics*, 8(6). Includes paper by Catsch on principles and trends.
7. "Toxicology: Inorganic." Chapter by Harry Foreman in *Annual Review of Pharmacology*, Vol. 2, 1962. Concerns stable metal complexing primarily.
8. "In Vivo Factors Influencing the Efficacy of Chelating Compounds as Therapeutic Agents for Metal Toxicity." H. Foreman. In *Drugs and Enzymes*. Proceedings of an international meeting in Prague, August 1963. Pergamon Press. A broad review of chemical principles and specific studies.
9. *Iron Metabolism*. An international symposium sponsored by CIBA, at Aix-en-Provence, France, July 1963. Springer-Verlag, Berlin. Much overlap between iron and substances of interest in this chapter.
10. "Prophylactic and Therapeutic Measures." Section in Hanford symposium, the *Biology of Radioiodine*, *Health Physics*, 9(12), 1963.
11. "Treatment for Removal of Inhaled Radioactive Particles." Section in Hanford symposium, *Inhaled Radioactive Particles and Gases*. *Health Physics*, 10(12), 1964.
12. *Radionuclide Contamination and Removal*. W. J. Bair and V. H. Smith (1969). In: *Progress in Nuclear Energy, Series XII*.
13. *Metal-DTPA Chelates in Biological Systems: A Bibliography*. V. H. Smith. Pacific Northwest Laboratory Report, BNWL-1657, 1972. In addition to the listings, which are arranged by element, the animal species under investigation are also listed.
14. "Acceleration of the Excretion of Actinide Elements." J. Vaughan et al. In chapter entitled "Metabolism and Biological Effects of Plutonium as a Bone Seeker." In: *Uranium, Plutonium, Transplutonic Elements, Handbook of Experimental Pharmacology, New Series*, Vol. 36, eds. H. C. Hodge, J. N. Stannard, and J. B. Hursh. Springer-Verlag, 1973, p. 471 et seq. Extensive summarization of EDTA, DTPA, BAETA, and others.
15. "Therapeutic Removal of Plutonium from the Lung." In chapter entitled "Plutonium in Soft Tissues with Emphasis on the Respiratory Tract." W. J. Bair et al. In: *Uranium, Plutonium, Transplutonic Elements, Handbook of Experimental Pharmacology, New Series*, Vol. 36, eds. H. C. Hodge, J. N. Stannard, and J. B. Hursh. Springer-Verlag, 1973, p. 562 et seq. Contains tabulation of tests for removal of inhaled plutonium dioxide.

(a) Several of these reviews are utilized in more depth in the text. If so, they are cited fully in the references. Otherwise, the above citations are sufficient to lead the reader to the volumes.

16. "Acceleration of the Excretion of Actinide Elements." In chapter entitled "Metabolism and Biological Effects of the Transplutonium Elements." P. W. Durbin. In: *Uranium, Plutonium, Transplutonic Elements, Handbook of Experimental Pharmacology, New Series, Vol. 36*, eds. H. C. Hodge, J. N. Stannard, and J. B. Hursh. Springer-Verlag, 1973, p. 853 et seq. Contains tabulation of DTPA work.
17. *Diagnosis and Treatment of Incorporated Radionuclides*. Proceedings of a WHO-IAEA seminar, held in Vienna in 1975. Contains several important review papers and international coverage. More on assessment than many earlier reviews.
18. *Chelation Therapy in Chronic Iron Overload*. A CIBA symposium. New York City, May 1977. Eds. C. Zaino and R. H. Roberts. Strathier Intercontinental Medical Book Corporation, New York. A series of very specialized papers.
19. *Treatment of Incorporated Transuranium Elements*. A report by V. Volf sponsored by WHO and IAEA and published as IAEA Technical Report Series No. 184, 1978. A comprehensive review.
20. *Selective Toxicity. The Physico-Chemical Basis of Therapy*. Adrian Albert. Sixth Edition. Chapman and Hall, London. A broad review of all aspects of selectivity, with a special section on metal-binding substances and the covalent bond.
21. "Actinide-Specific Sequestering Agents and Decontamination Applications." K. N. Raymond and W. L. Smith. In: *Structure and Bonding*, Vol. 43. Eds. Goodenough et al., Springer-Verlag, Berlin, 1981. Very detailed chemistry.
22. "Specific Sequestering Agents for the Actinides 4. Removal of ^{238}Pu (IV) from Mice by Sulfonated Tetrameric Catecharyl Amides." P. W. Durbin et al., *Radiat. Res.*, 81, pp. 170-187, 1980. While specific experiments are reported, much of the paper concerns general chemical problems.
23. *Management of Persons Accidentally Contaminated with Radionuclides*. G. L. Voelz, H. D. Bruner, T. A. Lincoln, V. H. Smith, H. Spencer, and N. Wald. NCRP Report 65, 1980.
24. "Therapy for Incorporated Radionuclides: Scope and Need." V. H. Smith. In: *Actinides in Man and Animals*, ed. M. E. Wrenn, 1981. RD Press, Salt Lake City.
25. "Status of Chelation Research: A Review." C. W. Mays, G. N. Taylor, R. D. Lloyd, and M. E. Wrenn. In: *Actinides in Man and Animals*, ed. M. E. Wrenn, 1981. RD Press, Salt Lake City.
26. "Recent Research on Decorporation Therapy at National Radiological Protection Board." G. N. Stradling and R. A. Bulman. In: *Actinides in Man and Animals*, ed. M. E. Wrenn, 1981. RD Press, Salt Lake City.
27. "Chelation Research at the Institute of Environmental Medicine, New York University Medical Center." Norman Cohen. In: *Actinides in Man and Animals*, ed. M. E. Wrenn, 1981. RD Press, Salt Lake City.
28. "Comments on Chelation Therapy." M. E. Wrenn. In: *Actinides in Man and Animals*, ed. M. E. Wrenn, 1981. RD Press, Salt Lake City.
29. "Removal of Inhaled Plutonium and Americium from Dogs Using Lung Gavage and DTPA." B. A. Muggenburg, J. A. Mewhinney, R. A. Guilmette, and R. O. McClellan. In: *Actinides in Man and Animals*, ed. M. E. Wrenn, 1981. RD Press, Salt Lake City.

IV. Experimental Work with Animals in the Postwar Era

In this section, we will give considerable detail and some summary tables that expand upon the preview given in section III. The approach is largely chronological for the major groupings. Emphasis is placed upon the principal developments during the years of AEC sponsorship, with less attempt to discuss recent work, which is readily available to the reader.

A. Zirconium

We have already cited the ideas put forward by Jack Schubert during and just after the Manhattan Engineer District days. We have shown a table from his 1947

publication comparing zirconium and sodium citrate effects on excretion of plutonium in rats (table 19.1).

More detailed reports from the ANL group compared effects of zirconium administration on plutonium and yttrium metabolism in both dog and rat (Schubert 1949; Schubert and White 1950b). Since plutonium is an alpha emitter and yttrium a beta emitter, the two radionuclides could be given and measured simultaneously in the same animal, thus eliminating some of the problems of animal-to-animal variation in excretion rates. They compared the effectiveness of "early" sodium citrate, "early" zirconium citrate, and "late" zirconium citrate. (a) The effects on both excretion and tissue contents are illustrated in figure 19.4A for plutonium and figure 19.4B for yttrium.

FIGURE 19.4A. Distribution and excretion of plutonium (Pu^{239}) in untreated and treated rats. Effect of zirconium and sodium citrate treatment on the distribution and excretion of $\text{Pu}(\text{IV})$ in rats six days after the intraperitoneal administration of the radioelement. (Redrawn from Schubert and White 1950b. Reprinted with permission of the American Society of Biological Chemists, copyright 1950.)

FIGURE 19.4B. Distribution and excretion of yttrium (Y^{91}). Effect of zirconium and sodium citrate treatment on the distribution and excretion of Y^{91} in rats six days after the intraperitoneal administration of the radioelement. (Redrawn from Schubert and White 1950b. Reprinted with permission of the American Society of Biological Chemists, copyright 1950.)

(a) "Early" = thirty minutes after intraperitoneal injection of the radionuclide. "Late" = seventy-two hours after intraperitoneal injection of the radionuclide.

Obviously, early treatment with zirconium citrate placed more plutonium in urine and resulted in less retention in carcass, femur, and liver, while late treatment had much less effect. There was little increase in fecal excretion of plutonium, but the zirconium, if given early, increased fecal excretion of yttrium. Note, too, how much more plutonium than yttrium was in liver.

The effects of zirconium in a single dog were as described earlier, with a surprisingly large effect on plutonium, which had been in residence for five months or even 2.5 yr. (Yttrium was not tried in the dog.)

Further work went from a single dose of zirconium to multiple doses and different dose levels (Schubert and White 1950b). Plutonium and yttrium excretion was proportional to the size of the dose, but reduction in skeletal content was essentially independent of the dosage given, above about 10 mg/kg body weight, and of the number of doses. Liver retention of plutonium increased with zirconium dose up to about 25 mg/kg body weight and then decreased. Liver retention of yttrium was little affected by changes in zirconium dosage.

These results, while not overwhelming, encouraged further trials, especially since the skeletal content of the animals was materially reduced, a sharp contrast to the attempts to reduce radium burdens by the techniques then at hand.^(a)

In a separate study, Schubert and White (1950a) showed that zirconium was effective in removing beryllium from rats. They used the radioisotope of beryllium, ^7Be .

By the time of the 1955 meeting at ANL on therapy of radioelement poisoning, the Marcia White listed above as a collaborator with Schubert had become Marcia White Rosenthal. Not only that, she edited the proceedings. At that meeting, she gave further information on the use of zirconium (Rosenthal 1956). She emphasized the growing evidence that the mechanism of zirconium action is a carrier effect on the *circulating* radioelement. Only the portion of the radionuclide in circulating blood (and perhaps extracellular fluid) becomes attached to the colloidal aggregates. The subsequent behavior of the element, i.e., disappearance from blood, deposition in tissues, and excretion is that of the zirconium-radioelement aggregate. She again stressed the effect of dosage size and regimen using many of the same animal data cited earlier. Zirconium treatment was ineffective for metals like strontium and magnesium.

Probably the most important lesson learned from this work, besides the presence of some effect, was the importance of prompt treatment.

Very soon, the Hanford group picked up the trail of zirconium therapy. They had much reason for interest since they were handling more plutonium than anyone else. In early annual reports of the Biology Division, Joffe and Temple (1953) and Wager and Temple (1954) (summarized by Thompson [1956]) found that zirconium produced even larger decreases in liver and skeletal contents of plutonium in the dog than in the rat. Also, it turned out that the dose needed to prevent bone deposition was lower than that needed to produce maximal excretion in the rat. Unfortunately, these doses seemed to *promote* accumulation in soft tissues. This work is summarized and referenced by Thompson (1967).^(b)

(a) This author can find no record of zirconium being tested for the removal of radium. Probably the fact that it did not mobilize calcium was taken as an indication it would not work for radium.

(b) A paper from Hanford by Katz, Weeks, and Oakley (1954), which compares various agents, also includes work on zirconium.

The Berkeley group apparently did not try zirconium for plutonium. However, they did test it for ^{90}Y (Copp and Kavin 1956). There was a marked increase in the excretion of ^{90}Y (16.4% to 91.2%) and very little bone retention in the treated animals.

Zirconium was also tested at the Naval Radiological Defense Laboratory (NRDL). Animal work was done by Stanton Cohn and utilized the variety of fission product surrogates, simulants, and prepared mixtures described in chapter 9. Cohn's work (1956) utilized zirconium largely in combination with chelating agents and will be described in section IV C.

By 1955, at least fourteen experiments with zirconium in animals (some of them parts of a several-experiment report) had been completed. These can be reviewed in the very useful table given in Appendix I of the ANL symposium volume (Report ANL-5584, 1956, see item 3 in "Review of Reviews").

Because of the urgency to have some form of treatment available for in-plant exposures, the Hanford group and others arranged to have zirconium available in proper form in their treatment rooms. It was used clinically both in the United States and the United Kingdom for a few cases, as described in section V.

To indicate that such readiness for therapy was more than academic, table 19.3 shows the existence of at least forty-five cases of low-level plutonium deposition at Hanford over a ten-year period up to about 1955. It is not stated which, if any, of these received therapy. Even if none did, the very presence of that number of cases bespeaks the need for having potential therapy available.

TABLE 19.3. Hanford Plutonium Deposition Cases in 10 Years

Per cent of MPL	First Detection By Routine Samples	First Detection After Known Incident	Route of Intake on Known Incident Cases				
			Inhala- tion	Inges- tion	Absorp- tion	Injec- tion	Un- known
<0.5	4	29	25	1	3		
0.5 to 1.0	7	4	2		2		
1.0 to 10	13	13	8		4	1	
10 to 20	4	6	5			1	
20 to 50	0	1	1				
50 to 100	2	0					
>100	0	0					
Partial Inter- pretation	15	2					2

Source: Reset from Thompson 1956, originally from H. M. Parker's paper at first Atoms for Peace Conference.

As we will see, the clinical experience with zirconium exposed problems not seen in the animal work and caused a considerable decrease in the urge to do further experimental work. Indeed, what we have reviewed, except for some

work aimed at interpretations of mechanism and combination therapy, about completes the story of zirconium therapy in animals in the United States.^(a)

B. British Anti-Lewisite

Experimental work in animals for removal of radionuclides with BAL (structure on page 1595) was definitive but not extensive. This stands in considerable contrast to the large amount of work done toward removal of stable heavy metals with BAL (cf. Doull, Klaussen, and Amdur 1980).

One of the earliest experiments aimed toward radionuclide removal concerned Thorotrast in rabbits. Björn E. W. Nordenström-Blomqvist, working at "a hospital in Stockholm," reported (1950) on the excretion of ThX (^{224}Ra) and MsTh (^{228}Ra) in urine. There was no effect of BAL on the excretion of these thorium decay products, nor was there any measurable excretion at all of thorium itself with or without BAL.

More experimental work was done on removal of polonium with BAL than on any other radionuclide. It was carried out at the University of Rochester, primarily by John B. Hursh. Like all of Hursh's work, which we have already seen in the chapters on radium (chapter 1), uranium (chapter 2), and polonium and thorium (chapter 4), it is carefully and authoritatively done, covers nearly all aspects of the problem, and forms a very neat package. The first work (Hursh 1949, 1951) concerned in part^(b) excretion and tissue distribution of ^{210}Po given as a single intravenous injection. Polonium excretion over a ten-day period was doubled on a dosage regimen where BAL was given at one hour after the polonium followed by three doses per day at intervals of no less than three hours for a total treatment period of three days. The average ten-day urinary excretion rate was 1.39% of the dose with BAL compared to 0.64% of the dose without BAL. Fecal excretion averaged 52.1% of the dose in ten days with BAL compared to 25.1% of the dose over a ten-day period without BAL. Thus, the most significant effect was via the increase in excretion in feces. Both rates reached their maxima at about five days, i.e., two days after cessation of treatment.

The changes in excretion were sufficient to reduce the total body burden, and, importantly, the BAL treatment caused a redistribution of polonium away from radiosensitive tissues like bone marrow, spleen, and testis and into a radio-resistant tissue, muscle. These results are shown in figure 19.5.^(c)

Investigation of the earlier changes in tissue distribution indicated that some of the changes shown in figure 19.5 at ten days after administration of the polonium also occurred at three hours. However, kidney and intestinal contents were *increased* in the BAL-treated animals at three hours, whereas at ten days, these organs were no different from those of controls. One of the most striking changes, which was measured by frequent sampling out to ten days, occurred in

(a) Interest continued in European laboratories somewhat longer. At the International Radiation Protection Association (IRPA) Congress on internal contamination published in 1973, some workers from Czechoslovakia discussed use of zirconium for removal of cerium and strontium (Severa 1973). There was a significant mobilization of cerium from both liver and bone, very little effect on strontium.

(b) The original University of Rochester Project Report (Hursh 1949) contains other information also, which will be considered presently.

(c) Polonium is not a bone seeker. The amounts shown in bone in figure 19.5 reflect primarily polonium in organic combination and in marrow.

FIGURE 19.5. The average tissue percent body content of polonium as determined in animals sacrificed at ten days is plotted in the first column for control rats and in the second column for five BAL-treated rats. The height of the shaded rectangle is equal to the average value; the superimposed open rectangle denotes the associated standard error. (Redrawn from Hursh 1951. Reprinted with permission of the Williams & Wilkins Co., Baltimore, Maryland, copyright 1951.)

the blood. The amount of polonium in blood was markedly diminished in the BAL-treated animals out to at least four, perhaps six days. We will return to this point.

To see if the changes in tissue distribution really make a difference in the effects of the polonium, Hursh (1952) carried out a survival experiment. Using the extensive background in acute toxicity work with polonium at Rochester, Hursh chose doses in the midlethal range and compared survival times as well as hematologic changes with and without BAL treatment. The treatment regimen was the same as in the earlier experiment (Hursh 1951). There was no doubt that the survival time was significantly increased (median, twenty-two to twenty-five days in untreated animals, eighty-nine days in the treated). This increase was larger than could be accounted for by the increased excretion alone (based on the established survival curves developed by Fink et al. and presented in chapter 4). The mobilization of polonium from radiation-sensitive tissue to a radioresistant tissue, such as muscle, must have played an important part. The blood red cell, white cell, and platelet counts were consistent also with the idea that spleen and bone marrow received a reduced radiation dose in the BAL-treated animals.

Hursh did not leave the work at the observational stage only however, a defect in some of the other research we have considered in this book. He went on to investigate possible mechanisms. In the 1951 study, he determined the polonium content of red cells, plasma, and plasma dialyzed for four hours against buffered saline. Despite the significant decrease of polonium content of both red cells and plasma, mentioned above, about seven times as much appeared in the plasma dialysate in BAL-treated rats. It could therefore be postulated that the BAL forms a soluble complex with polonium through the dithiol group in competition with its normal binding to tissues. This complex is presumed to filter readily through the kidney glomerulus and into the urine. Further, with the well-known tendency of polonium to form hydroxide colloids at neutral pH, which colloids are taken up by the reticuloendothelial system, it

can be further postulated that the diversion from spleen and bone marrow represents a reduction in these colloid moieties in favor of a soluble complex.^(a)

Hursh points out the contrast between the behavior of polonium bound to BAL and that of arsenic bound to BAL. In the latter case, there is a sharp rise in blood concentration of arsenic coupled with increased urinary excretion. The mobilization process is thus the converse of that seen with polonium. We will see that this is a common mechanism with the polyamino-polycarboxylic chelators of the EDTA type. Unfortunately, not all of the experimental work with EDTA-type chelators has gone as far as Hursh's work toward pinpointing a double mechanism: increased excretion and tissue redistribution.

Stannard and Haydon (1956) tested the effect of BAL on distribution and excretion of polonium given orally rather than intravenously. This was done since polonium exposures can be oral and a fraction of any inhalation exposure includes material cleared from the lung to the gut (see chapter 9). Effects on urinary excretion rates were not significant over a nine-day period. Fecal excretion was decreased (significant at $p \leq 0.05$), although not markedly (87.3% in nine days versus 93.4% in control animals). Tissue distribution of the absorbed polonium was *not* altered as it was after intravenously administered polonium. In fact, the most striking effect of BAL was an *increase in gastrointestinal absorption of polonium and consequent increased body retention of orally administered polonium*. Obviously, whatever solubilization occurred promoted absorption. The tissue distributions indicate the presence of a different form of polonium in blood after absorption from the gut, one not amenable to complexing with BAL, perhaps because it was already in a more soluble form (see chapter 4).

Further indications of such differences in state of polonium in the blood are found in earlier findings by Hursh (1949). For example, BAL was much less effective against polonium given subcutaneously than when given intravenously.^(b)

This work on polonium indicated possible therapeutic potential. However, the effect of route of administration and the fact that effects on inhaled polonium never got studied left some reasons for conservatism in possible application to humans.

The rest of the experimental work with BAL and radionuclides is largely negative. Kavin and Copp (1953) at Berkeley tried it for plutonium in rats. Kisielski, Norris, and Woodruff (1951) at Argonne tried it for ^{32}P and ^{90}Sr . Neuman and Allen (1949) tried it at Rochester for removal of uranium. All showed either no effect at all or short-lived unimpressive effects.

This series of negative results should not be construed as eliminating BAL as a potential therapeutic agent for radionuclides. Even though some of the more important potential contaminants were not affected, many elements remain untested even now. Also the radioisotopes of those elements whose mobilization in stable form has already been demonstrated would presumably

(a) Actually, more than one state of polonium exists in normal blood, an early diffusible state and poorly diffusible aggregates or combinations with protein or other carriers. The tight binding, once established, is difficult to reverse. Fortunately, it appears that the loosely bound fraction persists for appreciable periods and thus gives the BAL a chance to act.

(b) Some other sulfhydryl compounds, viz., "NDR-399" and "NDR-317" (see Hursh 1949) were more effective than BAL under these conditions.

behave similarly. The primary reason for termination of the work with BAL was the development of the more versatile chelators and a factor of unpleasantness in the use of BAL, viz., the typical unpleasant odor characteristic of many thiol compounds.^(a)

C. The Main-Line Chelators

By "main-line chelators" we mean those substances that have been used most frequently and have had, in general, the greatest success, particularly against contamination by the transuranics and the bone seekers in the fission product chain. These are EDTA, DTPA, TTHA, BAETA (table 19.2), and the additional polyamino-polycarboxylic acids and other substances.^(b)

1. The Actinide (Transuranic) Elements

a. Mobilization

We will begin with a tabular review of animal work directed toward removal or "decorporation"^(c) of plutonium and several other transuranium elements after intravenous administration of the radionuclide to rats. This review is shown as table 19.4, modified from the book by Volf (1978).

(a) *Note added in proof:* It turns out that neither the polonium nor the disulfhydryl sagas are really finished! At a meeting of the Society of Toxicology in Dallas in February 1988, Dr. H. V. Aposhian, University of Arizona (and a Rochester graduate) discussed successful removal of ^{210}Po with some newer sulfhydryl agents (Aposhian et al. 1988). In private communications to this author, he also cited the growing number of contamination incidents arising from leakage of polonium from static eliminator devices used in industry. For example, the *New York Times* of February 11, 1988, described the addition of "three more plants" to a growing list of incidents. None of them involved personal injury but have stimulated vigorous clean-up and preventive activities. Incidentally, it is stated that over twenty thousand of the static eliminator devices are in use. Those in plants producing food, drugs, or cosmetics have been recalled (in part, at least).

This resurgence of polonium's well-known tendency to escape from confinement has stimulated also more experimental work on decorporation. Aposhian et al. (1987) tried DMPS (2,3-dimercapto-1-propane-sulfuric acid Na-salt), DMSA (meso-dimercapto succinic acid), and DMPA (N-2,3 dimercapto propyl phthalamidic acid) for comparison with older agents. These are less toxic than BAL, more water soluble, and more effective. Studies on tissue distribution and excretion of polonium and survival times of treated rats showed all to be considerably better than a saline control, with DMPA the most promising. Studies on mechanisms are under way since it is thought that DMPA may have a more extensive intracellular distribution.

(b) Some of these are used in mixtures as indicated: TPHA-tetraethylenepentaamine heptaacetic acid; DTPP-diethylenetriaminepentamethylphosphonic acid; TH-tetracycline hydrochloride; BSA-1,2-dihydroxybenzene-3,5-disulphonic acid; NSA-1-(1-hydroxy-4 methyl-2-phenylazo)-2-naphthol-4-sulphonic acid; UM- β -methylumbelliferone; DFOA-desferrioxamine 8-methane sulphonate.

(c) We will use this term regularly, even though the purpose may sometimes be to prevent incorporation. We will use "decontamination" only in connection with the treatment of wounds.

Source: Modified from Volf 1978, Table X.

No one can say that this subject has not been adequately studied in animals! Consider also that the above tabulations refer only to systemic burdens of the radionuclides received parenterally. Behavior after intramuscular injection to simulate material entering from a wound will be considered separately. Note that, despite the volume of work, only a relatively few laboratories are involved: for the United States, Pacific Northwest Laboratory (PNL) (Richland, Washington); New York University (NYU); ANL (Chicago); and the University of Utah.^(a)

The figures of prime importance in these tables are, of course, the retention in tissues. A few conclusions can be drawn.

(a) Work in other countries is emphasized more in the tables shown here than has been our custom because of space limitations in this book. It has been a highly international enterprise.

1. Very considerable reductions of plutonium burdens can be effected if treatment is given early.
2. Ca-DTPA and BAETA are more effective than EDTA for plutonium.
3. The iron chelator, DFOA (see section III), is quite effective for plutonium, very much less so for americium and the others.
4. The less toxic Zn-DTPA (see later section) is less effective than Ca-DTPA for early treatment, whereas DFOA, TTHA, and BAETA are slightly superior.
5. Many combinations of dose and time have been tried. A more or less standardized procedure has been worked out and will be discussed in the section entitled "Experience in Man."
6. Species differences are seen. For example, the liver retains the transuranic elements longer in hamsters, dogs, and some monkey species than in mice and rats. Americium removal from Chinese hamster liver is more like that from rat than is that from the Syrian hamster. DTPA can remove quite different amounts of ^{241}Am from kidney in different species, even though excretion by untreated animals is about the same in all rodent species tried.
7. Actual removal rates are not always in line with the effective stability constants of the complexes in vitro.
8. Ca-DTPA administered early reduces retention of transuranics in rat bone in the order plutonium, californium, americium, curium.

Much of the preliminary work was done at Hanford and Los Alamos. As early as 1962, Ballou gave what he termed was a preliminary evaluation of the effectiveness of several chelating agents, viz., DTPA, TTHA (see table 19.2), and two strikingly similar substances, aminoethyl cyclohexyldiamine tetraacetic acid (ACDHA) and aminoethoxycyclohexylamine tetraacetic acid (ACHTA). The effectiveness of the various agents was quite different, for plutonium removal at least, despite similarities of chemical structure; ACHDPA and ACHTA were less effective than DTPA or TTHA. The early studies of Foreman at Los Alamos have already been cited (Foreman 1950, 1953, 1954, 1955).

Of further interest is work done at Richland on the removal of plutonium from the neonatal rat by Ca-DTPA (Smith and Sullivan 1978). Oral and parenteral routes were about equally effective, with some indication that absorption of DTPA is more facile from the neonatal rat gut. Other considerations regarding use of chelators in neonates will appear in section VI.

It was especially hoped that a chelating agent could be found that was effective when given orally. This would greatly simplify treatment. Using work of Ballou and colleagues (Ballou 1962a,b; Ballou and Palotay 1966) at Richland and of Taylor and Sowby at Sutton, in the United Kingdom (1962), as a basis, Volf (1978) concludes that only TTHA (triethylenetetraamine hexacetic acid) was equally effective when given orally as when given intraperitoneally.^(a)

Turning to intramuscular and simulated wound sites, the following quotation from Volf (1978) capsulizes the animal studies:

Until recently, considerable uncertainty existed about the route, dosage and rate of administration of the chelating agents in treating contaminated wounds and it was even pointed out that the treatment might induce enhanced absorption and subsequent deposition of the radionuclide in the body organs. It was, however,

(a) In much later work, Taylor and Volf (1980) demonstrated that this finding applied only to fairly high doses. If the chelators were given in low concentration in drinking water, DTPA proved equal to TTHA for plutonium and americium in rats.

suggested that even if absorption of the TU was enhanced, the systemic burden would not increase and even could be substantially lower than without treatment. This view is supported by the fact that TU injected intramuscularly as chelates with DTPA are absorbed almost completely and there is a minimal uptake of translocated TU by the organs, indicating a high stability of TU-DTPA *in vivo*.

Assuming that the effectiveness of DTPA in removing TU from a simulated puncture wound depends primarily on the local molar ratio of DTPA/TU and that DTPA excess can much more easily be achieved by local treatment with DTPA, a chelate injection directly into or close to the TU deposit should be more effective than the systemic treatment. This could indeed be proven experimentally for ^{239}Pu . Similar results have been reported for removal of ^{239}Pu by local injection of DFOA and for removal of ^{253}Es by Zn-DTPA. . . . The importance of ensuring infiltration of the ^{239}Pu deposit by the DTPA is evident from the greater consistency in enhancement of ^{239}Pu translocation achieved by the same chelate dose in a larger volume of solution. However, using a high-pressure spray-injector offers no advantage.

The local effectiveness of Ca-DTPA can be increased by combining it with sodium citrate or with DFOA: Up to about 90% of ^{239}Pu , injected intramuscularly as nitrate, could be removed by treatment 1 hour after administration and about 30% of the ^{239}Pu were removed from the simulated wounds even when treatment was delayed for as long as 3 weeks after contamination. Several other chelate combinations (DTPA plus tartrate, lactate, pyruvate or chinolinate, DFOA plus citrate) were less effective than DTPA or DFOA alone or even increased deposition of translocated ^{239}Pu in the organs. The enhanced effect of some of the combined chelating agents might be due to formation of mixed ligand complexes of plutonium.

It might be concluded that DTPA represents a useful means for supporting surgical therapy of TU-contaminated wounds. Systemic administration of DTPA would mainly reduce the uptake of translocated TU by the organs, whereas local chelate treatment with DTPA or with a suitable combination of chelates would be able to reduce the wound deposit, provided TU are present in a chelatable form, such as TU nitrate. It should be stressed that in large animal species as well as in man the chelating agent administered locally would be effective even if administered at a lower dose than that recommended for the systemic therapy; the local chelate injection should, therefore, be supplemented by a systemic one in order to ensure chelation of TU possibly absorbed into blood in a non-chelated form.

The use of DTPA therapy for the oxide form of ^{239}Pu in a contaminated wound appears to be of limited value. In dogs implanted with air-oxidized ^{239}Pu the only effect of systemic Ca-DTPA was seen in the kidney, while with high-fired ^{239}Pu oxide a reduction of ^{239}Pu in the skeleton was achieved comparable to that observed with ^{239}Pu nitrate. On the other hand, an enhancement in ^{239}Pu concentration following Ca-DTPA therapy was seen in the lung and thyroid after injection of the oxide forms of ^{239}Pu . However, treatment of ^{239}Pu -oxide deposits probably depends a lot on the particle size. In rats, the locally administered Ca-DTPA was capable of diminishing an intramuscular deposit formed by small ^{239}Pu -dioxide particles (<4 nm diameter), which appear *in vivo* even more soluble than a ^{239}Pu -nitrate deposit.

The rapid translocation of ^{239}Pu from a subcutaneous implantate to the proximal lymph node indicates the possibility of removing the latter, i.e. a therapeutic **lymphadenectomy**. However, in comparison with intact dogs, the liver, spleen and hepatic lymph node in the lymphadenectomized animals accumulated greater burdens of ^{239}Pu , which probably occurred before the residual lymph nodes began to function efficiently. Thus, in principle the therapeutic value of a lymphadenectomy for the management of ^{239}Pu -contaminated wounds could be improved mainly by chelation therapy and/or excision of the contaminated wound to minimize the ^{239}Pu reservoir.

(Volf 1978, pp. 33 and 37)

A summary table showing a comparison of systemic and local treatments of intramuscular deposits of transuranium elements in rats illustrates these statements (table 19.7).

Durbin (1973), in her monumental review of all the biomedical work to 1972 on the transplutonic elements, considered the status of therapy. She cites a few experiments not contained even in the Volf review (tables 19.4 through 19.7). These concerned ^{241}Am , ^{253}Es , and ^{252}Cf , which are shown in table 19.8 modified from Durbin's paper. The chelating agent was DTPA.

The amount of the radionuclide remaining in bone, as a percentage of the control, is satisfyingly reduced by the treatment in most cases. The disappointments appear largely when the treatment time is short, but there is considerable variability among the experiments. The aerosol treatment (Nénot, Morin, and Lafuma 1971a,b) seemed to require the longest period of use. A slow release implant technique for Zn-DTPA has been devised by Calder et al. at Utah (1978). Further work at Utah considers the variables of form of plutonium, frequency of administration, etc. (Lloyd et al. 1978; Taylor et al. 1978).

Not shown in the tabular material is the fact that fasting had little or no influence on effectiveness of a chelator like DTPA on excretion of plutonium, nor did it change the tissue distribution (Sanders and Meier 1973).

It is clear from the information cited in this section on actinide therapy that the chelators in the EDTA, DTPA class are much more effective than most of the other modalities we have discussed thus far for decorporation of actinide-type elements. Also, the transplutonium elements appear to be transportable to a considerable degree, frequently more easily than plutonium.

b. Reduction of Biological Effects

In considering Hursh's work on BAL, we lauded his extension of the observations beyond the increase in excretion and redistribution among the tissues to measures of relative effects. We commented that this ultimate test of the usefulness of therapy has been notably absent in much of the experimental work on chelation therapy. This has been true, unfortunately, of the work with actinides as well.^(a) In Volf's review (1978), out of 353 references, only 3 concern studies directed toward evaluating the potential reduction in toxicity of the

(a) Dr. Walter Weyzen, who was program manager of the cognizant section in the Department of Energy, often remarked that the goal of chelation research should be the reduction of risk, not just the removal of radioactivity (Mays et al. 1981).

deposited actinide elements.^(a) It now appears that enough work has been done on determining the reduction in effects to prove that such really does occur. Work is continuing, most of it abroad.

We should take note of the reasons a positive result (i.e., reduction in effect) would not inevitably follow the reduction in tissue burdens. The Karlsruhe school has pointed out the forces that might operate against a therapeutic gain. First, tumor incidence reaches a distinct maximum as a function of the amount of deposited radionuclide. This reflects the vectors of carcinogenesis on the one hand and cell killing on the other. Conceivably, a reduction in bone deposition could increase tumor production if the amount of radionuclide present originally was beyond the maximum, i.e., in the region where cell killing overbalanced carcinogenesis. Similarly, the net result might be no effect at all. Obviously, delayed treatment would be expected to have less effect on tumor incidence just as it has on decorporation. Examples exist of differences consistent with these ideas (Volf 1978).

To illustrate clearly therapeutic end-results, we will examine two instances of toxicity measurements with ^{239}Pu . The first concerns DTPA given by inhalation after inhalation of plutonium citrate in rats. It is shown in table 19.9.

TABLE 19.9. Effect of DTPA on Subacute ^{239}Pu -Toxicity in Rats

	Controls	Prophylactic DTPA Inhalation
Survival (d)	184	470
Lung dose (rad)	2230	650-950
Skeletal dose (rad)	374	315
Pneumosclerosis (%)		
Light	9	44
Severe	62	10
Nephrosclerosis (%)	21	25
Bone marrow aplasia (%)	21	2

Ca-DTPA (2.4 mg) was inhaled 30 min before a single ^{239}Pu citrate inhalation, resulting in an initial lung burden of $\sim 0.5 \mu\text{Ci } ^{239}\text{Pu/g}$. 75 control and 60 treated rats.

Source: Reset from Volf 1978, Table XIV.

Obviously, the treatment increased survival, reduced the pneumosclerosis from heavy to light, and had a significant effect on bone marrow aplasia. Effects in kidney (nephrosclerosis) were not reduced.

(a) The reasons for this hiatus have never been formally declared. The effects work requires long periods and much larger expenditures per unit of information gained than work on distribution and excretion. Funds for therapy give quicker results if metabolic endpoints are used. Furthermore, reductions in bone and soft-tissue depositions bespeak reductions in toxicity. Nevertheless, we have been surprised before, and there are enough factors tending in opposing directions in this field that concrete proof of a therapeutic gain is clearly needed. It may have come from the experience with man.

The second example concerns tumor incidence in both bone and soft tissue, which was examined in detail for both monomeric and polymeric plutonium by Rosenthal and Lindenbaum (1967) at ANL. A summary is shown in figure 19.6A and B.

FIGURE 19.6A. Cumulative bone tumor incidences, expressed as percent of mice with bone tumors and plotted at 25-day intervals, in mice given monomeric plutonium followed by DTPA for 12 days. (Redrawn from Rosenthal and Lindenbaum 1967. Reprinted with permission of Academic Press, Orlando, Florida, copyright 1967.)

FIGURE 19.6B. Effects of twelve daily intraperitoneal injections of 500 mg of DTPA per kilogram, initiated either 3 days or 1 hr after intravenous administration to mice of either $0.0643 \mu\text{Ci}$ ($\sim 2.6 \mu\text{Ci/kg}$) of monomeric plutonium or $0.0587 \mu\text{Ci}$ ($\sim 2.6 \mu\text{Ci/kg}$) of a polymeric form of plutonium (1.6). Control mice (C) received plutonium and twelve injections of saline solution. Bone tumor incidence in each DTPA-treated group is shown both at the time of death of the last plutonium-control mouse at 501 days for monomeric, and 515 days for polymeric plutonium) and at the time of death of the last treated mouse. The amount of plutonium shown in the bone is that measured in two femurs $\times 10$. (Redrawn from Rosenthal and Lindenbaum 1967. Reprinted with permission of Academic Press, Orlando, Florida, copyright 1967.)

Again, it is clear that time of administration of the chelator is critical. It will be noted that the percentage of animals bearing tumors of bone appeared to be delayed (the principal effect), and total incidence was also reduced somewhat. This was in the mice receiving monomeric plutonium, the most carcinogenic form (figure 19.6A). The lifetime bone tumor incidence is reduced also for polymeric plutonium. A rough correlation to bone content of plutonium can be seen in figure 19.6B. The effects of delay in treatment can be seen in the greater amelioration of effects as well as in the greater reduction of bone content of plutonium with earlier injections (figure 19.6B).

The fact that changes might occur in the microdistribution of the plutonium deposited in bone was demonstrated by Polig (1976a,b) working at Karlsruhe. Autoradiograms confirmed the ideas developed from the bone chemistry, viz., that the chelating agent (Ca-DTPA) brought about the most marked reductions in deposition of the transuranium elements in the areas of newly formed bone, metaphysis and diaphysis, and less reduction in the deposits buried and not as susceptible to removal by these chelating agents. To the degree that the buried deposits are the less important to tumor production, this shift in pattern bespeaks a reduction of effects, perhaps out of proportion to the reduction of bone content.

This small amount of work on reduction of effects does not allow much quantitation. It does indicate that benefits have been demonstrated directly. In retrospect, it appears that the resources expended on fine-tuning of the effects of these chelators on distribution and excretion of radionuclides in a variety of systems and on many dosage regimens may have gone further than the needs of the times. More effort toward obtaining quantitative data on reduction of effect might well have replaced some of the metabolic experiments. It is probably futile to recommend expansion of the effects work now since funding for nearly all work on radionuclide therapy in the United States has been cut off. Nevertheless, the prosecution of such studies should be earmarked for pursuance if, as, and when funding becomes available. The work in progress at Utah thus becomes of special importance.^(a)

c. Removal of Inhaled Actinides

Some major efforts were expended on means of removal of the actinide elements after inhalation and deposition in the lung and accessory respiratory structures. This was concentrated in the laboratories most involved with pulmonary radiotoxicology, especially at Hanford and the Lovelace Foundation Inhalation Toxicology Research Institute (see chapters 8 and 9).

It is more convenient to discuss all aspects of the removal of inhaled radionuclides together. Hence, this important portion of the therapeutic approaches to actinide removal will be postponed to section IV F, except for the small portion included in table 19.9.

2. Use of Main-Line Chelators for Removal of Other Elements

The chelating agents have been tried and used predominantly for the actinide elements. The tabular summaries above testify to this. The laboratories

a) *Note added in proof:* Very recently, the Utah group (Jones et al. 1986) presented clear evidence for a reduction in cancer risk from ²³⁹Pu by chelation therapy. This is a fully quantitative and detailed study in the dog and extends the work in the female mouse by Rosenthal and Lindenbaum shown on page 1619.

concerned were not unaware of the importance of decorporation therapy for other radionuclide groups, but EDTA, DTPA, etc., arrived on the scene at the same time as major concern for plutonium and the actinides, i.e., the potential for a "plutonium economy." Nevertheless, some experimental work was done toward decorporation of radionuclides other than the actinides. This will be reviewed briefly in this section. Frequently, the chelator was only part of a multicomponent mixture.

Most of the work was done in the earlier postwar years, i.e., in the 1950s and 1960s. Much of it was stimulated by the problems initiated by fallout from weapons tests. Probably the best single compendium on the use of the EDTA, DTPA, and similar chelators for decorporation of radionuclides such as strontium, ruthenium, cerium, and rare earths in general is found in the scientific meeting sponsored by the International Atomic Energy Agency-World Health Organization (IAEA-WHO) in Vienna in 1962 (IAEA 1963). It considers both animal work and clinical trials. Our interest here is the experimental work with animals.

Copp and Kavin (1956), working at Berkeley, tried Ca-EDTA for removal of ^{91}Y and ^{90}Sr from rats, including its influence on uptake from wounds. There was reduced absorption from the wound and enhanced urinary excretion in the case of yttrium. The Ca-EDTA had little effect on strontium uptake or removal.

Jenifer Jowsey, a visiting investigator from the United Kingdom working at the University of Chicago (ANL), showed reduced retention of yttrium in bone of rabbits receiving EDTA. She also showed by autoradiography that the yttrium was removed primarily from the metaphyseal trabeculae. Repeated injections prevented the secondary deposition of the radionuclide below the epiphyseal plate usually associated with bone remodeling (Jowsey, 1956).

Cohn (1956), whose work from the NRDL has already been cited, chose ^{91}Y as a prototype for the lanthanide rare-earth group of fission products. He tried a mixture of sodium and calcium EDTA in mice and found greatly increased amounts of yttrium in the excreta, with reduced deposition in liver and muscle. For treatment of radiostrontium, he used BAL in combination with EDTA and also used zirconium with EDTA. The mixtures were used because it was already known that strontium was not much affected by the agents singly. The mixtures were slightly more effective, but the results, using ^{90}Sr , were of marginal biological significance.

Cohn then turned to three-day-old mixed fission products in a fallout simulant. The work involved a complex protocol whose features and results are shown in figure 19.7A and B taken from Cohn's work. A few treatments increased excretion and reduced somewhat bone and liver deposition of these mixed fission products. Zirconium was clearly better than EDTA in this case. However, the data illustrate vividly how much effect small changes in regimen have on the final result (see also Cohn and Gong 1953).

The Hanford group used primarily the inhalation route and studied ruthenium, iodine vapor, strontium sulfate, and cerium oxide. (As stated above, we will review the inhalation work separately.) Some noninhalation work on animals was done at Hanford on ruthenium (Smith 1965) and promethium (Smith 1970b,c,d), nearly all of it reported in annual progress reports. There was also experimental work on promethium in man (Palmer and Nelson 1970).

Fried and Schubert at Argonne (1961) tried EDTA and DTPA for decorporation of thorium, largely in colloidal form, from rats and mice. The results were marginal.

Herta Spencer at the Hines Veterans Hospital in Hines, Illinois, did some animal work with rare earths as a prelude to her quite extensive metabolic studies on man (see Spencer and Rosoff 1963).^(a)

Work at Los Alamos by Harry Foreman's group (Foreman and Finnegan 1957) used deposition and excretion of rare earth elements as a vehicle for analyzing the relationship between the effect of chelating agents in vivo and the stability constants determined in vitro. They used ^{144}Ce , ^{147}Pm , ^{150}Tb , ^{91}Y , and ^{170}Tm , with EDTA as the chelator. In the many symposia we have cited, the physical chemistry of the chelators was a major subject; one we do not have space to describe. There are separate affinity and stability constants for each of the several processes involved. Foreman decided that, for his system, two of the affinity constants were of primary importance, the affinity of EDTA for the various rare earths, and the stability constant of the rare earth natural binding agent complex. In figure 19.8, we see a plot of a derivative of these two constants (plotted as the log of the stability constant for the complex, EDTA-rare earth), which varies with the molecular weight of the rare earth element concerned, against the chelating effectiveness, given as a ratio of control to treated.^(b)

FIGURE 19.8. The relationship of stability constants to chelating effectiveness in the body. Detailed in the text. (Redrawn from Foreman and Finnegan 1957. Reprinted with permission of the American Society of Biological Chemists, Bethesda, Maryland, copyright 1957.)

The rats treated with Ca-EDTA showed real differences in tissue content after treatment at values of the log K_{my} ^(c) above 16.6 or between promethium and terbium. The largest effect was in the long bones and the liver and in the total excretion. The magnitude of the maximum effect on the urine is quite comparable to the effects of EDTA in mobilization of the actinides. Of interest is the fact that the "turnover point" in the curve can be shifted by altering the dose of the chelating agent, i.e., the magnitude of the effect can be altered. (This, of course, reaches a maximum.)

- (a) The texts of the reports cited show only data for man, but there are references from the same laboratory to work with animals.
- (b) Although the figure as presented by Foreman and Finnegan does not so state, it appears from the data that the average effectiveness ratio given is some sort of composite from data on urine, feces, liver, spleen, long bones, and the remainder tissues.
- (c) K_{my} represents the stability constant for the metal and the chelating agent as explained by Foreman and Finnegan (1957).

Earlier work by Foreman, done while he was at Berkeley on a postdoctoral fellowship, compared the effectiveness of EDTA in hastening urinary excretion of ^{91}Y and ^{239}Pu (Foreman 1953). Both radionuclides were mobilized in terms of increases in urinary excretion; the effect on plutonium seeming to be somewhat longer lasting. In neither case, even with a tenfold increase in urinary excretion, was the tissue burden reduced to the extent hoped for.

Foreman postulates from the in-vitro data that chelating agents of the EDTA type would not mobilize strontium or radium because calcium forms a stronger chelate. This prediction has been borne out in animal work already cited, in work abroad, and in the clinical trials.

At the University of Utah, almost all of the work concerns actinides. However, Stover and colleagues (Stover et al., 1958; Stover, Ruhmann, and Atherton 1966) tried EDTA in two dogs that had received ^{228}Th two years previously. There was no enhancement of excretion of the daughter product, ^{224}Ra , but there was a marked effect on urinary excretion of ^{212}Pb . This was not unexpected since the stability constant between lead and EDTA is much higher than that for calcium or radium. Indeed, this fact accounts for the considerable effectiveness of the main-line chelators in decorporation of lead, a story we cannot present but one that took place in many American laboratories before and at the same time we have been describing.

At New York University, primary interests were also in the actinides, especially americium. However, they also studied the effects of Ca-EDTA on mobilization of ^{210}Pb . Using the baboon, they concentrated on oral administration of the chelator. They achieved a doubling of the urinary excretion of ^{210}Pb (Wrenn 1977). (a)

A rather thorough study of the decorporation of radiocobalt was carried out by Fisher and Dunavant at the University of Florida (1978). They were interested in possible contamination incidents with ^{59}Co and ^{60}Co and were concerned that therapeutic measures for these had not been established. One reason for this hiatus was a mistake in the officially promulgated retention time for cobalt in man. The International Commission on Radiological Protection (ICRP) 1959 biological half-life was given as 9.5 days, based on limited animal studies. Later work indicated several components in the retention function with some long-lived fractions that predicted an average biological half-life in man of about seven years. Fisher and Dunavant tried five chelators and chelating mixtures. The old standbys were quite ineffective for decorporation of cobalt. However, a chelator with cobalt integrated into the structure, viz., CoNa_3DTPA reduced the radiocobalt body burden to 66% and the liver burden to 40% of the controls in mice. The reasons for the ineffectiveness of CaNa_3DTPA and ZnNa_3DTPA and the better results with CoNa_3DTPA are considered to lie in the special chemistry of cobalt as a transition metal.

Despite the studies cited, it must be observed that animal work in American laboratories on chelation of radionuclides other than the actinides has been

(a) This experiment was directed at more than the objective of testing the chelator. The NYU group was interested in means of identifying uranium miners with significant skeletal burdens of ^{210}Pb resulting from exposure to radon daughter products. The urinary excretion of lead from skeletal stores is so slow that they used the chelator to provoke excretion and thus help identify miners to be measured by in-vivo scintillation counting. They used the oral route since it was their plan to use it for the miners. It is likely they could have achieved higher excretion rates by parenteral injection of the chelator.

rather sparse. By contrast, rather considerable efforts took place in the United Kingdom, France, and West Germany. Perhaps the most efficient way to enter that literature is through the excellent papers by Nelson (1963) on strontium and by Catsch and Seidl (1963) and Bruce (1963) concerning rare earths and ruthenium. These are in the IAEA symposium already cited. Each of these papers gives a cogent summary of the world's literature.

By contrast, much work was done in American and other laboratories on the effectiveness of the other pharmacological agents and on modifications of diet, particularly on strontium uptake and removal. Also, American laboratories did fairly extensive studies in man toward removal of fission products and rare earths as well as the actinides, as we shall see in section V.

D. Modification of the Main-Line Chelators and Substitutions

1. LICAMs

Recently, there have been developments in compounds with tetracatechoyl ligands (cyclic and linear) and tetracatechoyl amides (CYCAMs or LICAMs). These specific sequestering agents were the result of work by a group of chemists at Berkeley (Weitl et al. 1978; Raymond and Smith 1981). They have low reactivity with divalent metals and thus cause less depletion of these than DTPA.

The effectiveness of these new agents, i.e., one called LICAM-S^(a) in decorporating plutonium has been examined in depth by Durbin et al. (1980). The emphasis in this work was on the effect of variations in the chemical structure and is more detailed than we can present here. The conclusion was that electron donor groups that bind Fe (III) preferentially also bind Pu (IV) efficiently. They bound ²³⁸Pu in valence state IV while it was still in body fluids and effectively prevented further deposition in skeletal tissues of mice. Several of these ligands also prevented deposition in liver, but they could not remove plutonium once deposited in liver. On the other hand, they could remove as much or even more plutonium from the skeleton as an equimolar amount of CaNa₂DTPA. The linear configurations (LICAMs) were somewhat more effective than cyclic configurations (CYCAMs). Acute toxicity was not marked in mice, although some members showed measurable toxicity.

The work was picked up using dogs in collaborative efforts between the groups at Utah (Mays, Bruenger, Lloyd, Taylor, and Wrenn) and the Berkeley group (Durbin and others). The LICAM-S was prepared by the group at Berkeley. They compared effectiveness against both plutonium and americium with results illustrated in table 19.10. The comparison involved Ca-DTPA and two fairly recently synthesized LICAM compounds.^(b)

Obviously, the LICAM-S was somewhat better than Ca-DTPA in terms of reducing whole-body retention of plutonium, but much less effective with americium. A mixture of LICAM-S and Ca-DTPA reduced plutonium retention still further but was about the same as Ca-DTPA alone against americium.

Thus, these compounds show promise for specific uses, but may not be as generally useful as the polyamino-polycarboxylic compounds. Their lack of

(a) N¹, N⁵, N¹⁰, N¹⁴-tetra (2, 3-dihydrox-5-sulfobenzoyl)-tetraazatetradecane.

(b) Modifications of the structure were made to attempt to overcome nephrotoxicity of some of the earlier LICAM compounds reported by F. W. Bruenger at Utah in unpublished observations. The methods of preparation are described in the references given.

TABLE 19.10. Effectiveness of Various Chelating Agents on the Removal of Plutonium and Americium from Beagles

Treatment*	Total-body retention at 7 days	
	Plutonium % \pm S.D.	Americium % \pm S.D.
Untreated	87 \pm 5	89 \pm 6
CaDTPA	29.7 \pm 6.5	20.1 \pm 1.1
LICAM-C	11.8 \pm 0.6	71.6 \pm 2.4
LICAM-S	13.7 \pm 0.6	67.2 \pm 1.5
LICAM-S plus CaDTPA	11.6 \pm 1.3	20.9 \pm 1.2

* 30 μ mole/kg of each agent was injected intravenously at 30 minutes.

binding to essential divalent metals and thus reduced tendency to deplete the body stores of essential metals may be the chief advantage of the LICAM group. *Work on them should be continued.*

2. Lipophilic Compounds

As work progressed at a number of laboratories on the metabolism of the chelating agents themselves, using compounds labeled with a radioactive tracer, it became clear that a small but significant portion of the agent remained in the body considerably longer than the main portion. (The latter was degraded by metabolic processes in relatively short times—half-period about two hours.) The longer-lasting portion was postulated to be within cells, while the rest remained outside of cells. On this basis, attempts were made to modify the chelators to promote penetration into cells. Increasing the fat solubility is one approach to this end. Hence, "lipophilic compounds" were developed. Since it was also apparent in work at Utah and in the United Kingdom (see chapter 8) that the actinides were associated with lysosomes in rat and dog, at least, the idea gained further credence.

One approach was that taken at ANL by Marcia Rosenthal and colleagues. They (Rahman, Rosenthal, and Cerny 1973; Rosenthal et al. 1975) prepared lipid spherules from lecithin, called liposomes, and encapsulated DTPA within them in bimolecular layers of lipid separated by an aqueous phase.^(a) They used EDTA labeled with ^{14}C for some of the work and demonstrated markedly increased uptake and retention of the agent in liver, spleen, lungs, and bone marrow of mice. They demonstrated improved removal of polymeric plutonium from mouse liver and skeleton and increased urinary excretion. They also found that relatively low doses were as effective as higher doses. A sample of the results is given in figure 19.9, taken from the most successful experiment of

(a) The methods of preparation are described in separate publications cited in the references given.

FIGURE 19.9. Effect of liposome-encapsulated DTPA or of nonencapsulated DTPA on the skeletal content of Pu (the amount in both femurs $\times 13$). Liposome-encapsulated DTPA, 100 mg/kg, was injected intravenously at 3 days, or at 3 and 6 days, after injection of Pu. Nonencapsulated DTPA, was injected intraperitoneally at 3 days after Pu. (Redrawn from Rosenthal et al. 1975. Reprinted with permission of Academic Press, Orlando, Florida, copyright 1975.)

Rosenthal et al. (1975). Relative removal rates were not quite so different in other experiments using different dosage regimens.

Effectiveness with long-standing deposits of plutonium is a matter for conjecture. The Argonne workers tried injections out to twenty-four days after the plutonium was given, but there was no work with the long-term plutonium burdens of interest in many clinical cases. It is with these that the intracellular penetration might make the most difference.

Interest in the intracellular portion of deposited radionuclides and the corresponding intracellular fraction of chelating agents has continued at Argonne, principally in Arthur Lindenbaum's group (Bhattacharyya, Peterson, and Lindenbaum 1978a,b; Bhattacharyya and Peterson 1979). Bhattacharyya, among others, has been interested in penetration of DTPA into liver cells. It may well be that most of the extra plutonium mobilized from liver to bile is handled by intracellular DTPA. It is also clear that chelators can enter macrophages and cells in tissue culture (see, for example, work from Battelle by Sanders and by Robinson et al., quoted by Mays et al. [1981]).

In the United Kingdom, a partially lyophilic derivative of DTPA was developed. It had a structure not too different from the main-line chelators except for very long aliphatic chains, which presumably increased lipid solubility. The substance was named "Puchel," and its structure is shown in figure 19:10, taken from the summary report of Stradling and Bulman (1981).

FIGURE 19.10. The structure of Puchel. (Redrawn from Stradling and Bulman 1981. Reprinted with permission of RD Press, University of Utah, Salt Lake City, Utah, copyright 1981.)

As Stradling and Bulman summarized, with earlier literature cited therein, this derivative of DTPA was superior to DTPA in enhancing the clearance of plutonium from the liver of hamsters, even if given up to ten days after the plutonium. Perhaps the most promising area for Puchel is found in its ability to move plutonium and americium from the lungs. Liposomally entrapped DTPA did not seem to have this property.

The mechanisms of action of DTPA and Puchel appear to be quite different. Puchel clears most of plutonium or americium to the feces, while the urine carries most of the DTPA-cleared activity.

The ability of Puchel to decorporate radioelements from bone appears yet to be evaluated.

Neither of these promising compounds, liposomally encapsulated DTPA or Puchel, has reached commercial production^(a) or clinical evaluation as of the time of this writing. As Mays et al. pointed out (1981), the importance of intracellular decorporation and of getting chelators inside cells has only recently been appreciated.^(b) We may see some interesting developments along these lines, although the cutoff of funds for chelation research (see Smith 1981) cannot help but retard new developments.

A summary of animal research aimed at improving the intracellular penetration of DTPA was tabulated by Volf (1978). Some results with transuranic elements (which do not include the more recent work described above) are reproduced as table 19.11.

Source: Modified from Volf 1978, Table XII.

As indicated by the column labeled "TU retention," the success of compounds or combinations intended to increase cellular penetration was greater in the case of liver than for skeleton. This is not surprising since the skeletal binding process involves more complex reactions than simply the question of being within or outside of cells. The increase in effectiveness by going to fat soluble forms is not very consistent.

3. Adjunctive and Mixed-Ligand Therapy

a. Adjunctive Therapy

We will soon review approaches to therapy of deposited radionuclides by methods quite different from the use of chelators. In this section, we will consider briefly additional work in which chelators have been tried in combination with other quite different agents and also work in which chelators or closely related substances have been tried in combination. We will call the first adjunctive and the second mixed-ligand therapy. The reasoning behind some of the combinations will be obvious. In other cases, the *raison d'être* does not stand out. We will try to include a few words of explanation in these latter cases.

Again we can start with a convenient summary table from the book by Volf (1978). In table 19.12, we find a summary of most of the work through the mid-1970s using adjuncts to DTPA. (Some work was done with adjuncts to other chelators, but DTPA was the most used.) This summary suffices for our needs. Obviously, the bulk of the work comes from Argonne and Hanford.

The reasoning behind some of the adjuncts is as follows:

Glucan—from cell walls of yeast. Postulated to facilitate disruption of intracellular aggregates of plutonium and other transuranics in liver. Action demonstrated by autoradiography.

Pyran—facilitates lipid solubility.

Triton—a detergent with a possibly different mode of action, a lysomotropic agent.

The reasoning for the use of urethane and hydroxyquinoline is somewhat obscure.

TABLE 19.12. Effect of Various Factors as Adjuncts to DTPA After Injection of Plutonium. [Author, date, and location in bold.]

Source: Modified from Volf 1978, Table XIII.

A scan of table 19.12 indicates some degree of enhancement of the effectiveness of DTPA in some cases. However, the effect is modest at best. It is more notable in liver than in bone, as might be expected from the much greater role of phagocytosis in the movement of entrapped radionuclides in the liver.

Not shown in the table is the fact that some of the additives (e.g., glucan) have significant toxicity by themselves. This led to searches for less toxic derivatives.

Other combination therapies were reviewed briefly in earlier sections, and many more will appear when we consider the nonchelator approaches. The ones considered in this section are a sample of those where there was overt attention to providing an adjunct to one of the main-line chelators.

b. Mixed-Ligand Therapy

Mixed-ligand therapy is similar to adjunctive therapy except that the two agents are expected to act by chelation rather than by mixed mechanisms described above for adjunctive therapy. We have already seen some examples in reviewing the earlier work on citrate. The most notable example, and the one usually meant by the term "mixed-ligand therapy," involves one of the few scientific scandals in the field of radioisotope toxicology.

In 1978, Schubert, who had by now shifted from the large research laboratories to a small liberal arts college in Holland, Michigan (Holland College), published a paper in *Nature* with a collaborator, S. K. Derr, on therapy with salicylic acid and Ca-EDTA in combinations (Schubert and Derr 1978). The combination was reported to remove virtually *all* of the plutonium burden from mice, including that deposited firmly in bone. This was hailed as a major breakthrough in chelation therapy. As detailed by Mays et al. (1981), nearly all of the world's laboratories working on chelation therapy for deposited radionuclides dropped everything to test the mixed-ligand hypothesis. This included Argonne, Battelle-Northwest, and the University of Utah in the United States; the Medical Research Council Radiobiology Unit and the National Radiological Protection Board in the United Kingdom; and the group at Karlsruhe in West Germany. The spectacular results could not be confirmed. The best that could be found

was a residual retention of about 30%, not much below that found in the best of the other chelation experiments. It was never 0% as claimed in the original paper.

In view of these conflicting findings, Schubert repeated the work and checked out the older data. To his dismay, he found that major portions of the data had apparently been invented by Derr! Schubert subsequently published notes retracting the original findings and giving the correct information. He also checked out catechol and tiron in combinations with DTPA and EDTA and found no significant difference from either compound alone (Schubert 1979, 1980).

As Mays points out, this episode probably cost the research organizations a half a million dollars, as well as delaying work in progress.^(a) It is especially unfortunate that it should have happened to Jack Schubert, who essentially initiated the idea of complex formation and pioneered the field along with Harry Foreman. He should be remembered for these contributions much more than for the mixed-ligand fiasco, in which he was not only blameless, but acted with responsibility and dispatch to clear the air.

E. Nonchelating Therapy

We are now ready to consider work done using means other than complexing or chelation to prevent deposition or to promote removal of radionuclides. This extends back to the work with radium done in the 1930s at MIT-MGH^(b) using diet, hormones, vitamin D, etc., to alter calcium metabolism. It includes a very miscellaneous collection of approaches. Since much of it has already been touched upon, and much of it is obvious, we will make no attempt at a complete review.

In contrast to the approaches to actinide therapy that received their major attention along with the development of the main-line chelators, much of the work using nonchelation methods relates to other radionuclide groups, especially those that, like strontium, behave like calcium in the body. Some of it applies to mobilization from the lung and will be considered in the section on therapy of inhaled radionuclides.

A very satisfying general review, which includes the agents and processes pertinent to this section, is the one by Bair and Smith (1969). They mention, among others, the following approaches to therapy:

1. decorporation by physical processes—e.g., whole-blood transfusions, use of an artificial kidney with an ion exchange column, surgical excision of contaminated wounds, pulmonary or peritoneal lavage, etc.
2. ionic dilution—e.g., addition of stable forms of the radioelement (i.e., isotope dilution), use of elements with closely related metabolic properties.
3. biological means for decorporation—e.g., alteration of physiological processes, either to mobilize the element, to stimulate recovery processes, or to prevent its deposition. This includes manipulation of diet.
4. radioprotective agents—e.g., cystamine and other radical scavengers to ameliorate the radiation effects (see the introduction to this chapter).

(a) It will be recalled that startling, but not necessarily dishonest claims, in the area of radiation standards, effects of fallout, etc., have cost the research community much larger sums. See chapters 12 and 16.

(b) See chapter 1 and section I A.

Among the examples of ionic dilution, the use of stable iodine to prevent uptake of radioiodine by the thyroid has already been discussed. Decreased retention of tritium by drinking large quantities of water with or without administration of a diuretic and use of Mg^{2+} for decreasing radiostrontium levels in bone are further examples.

For a review of the relatively early work, we turn to the ANL meeting in 1955. Animal work reviewed therein includes the following approaches in addition to the complexers and chelators already described:

		Rating(a)
For ^{239}Pu	Ti citrate (Rosenthal, Argonne)	+++
	Mn gluconate (Rosenthal, Argonne)	++
	Fe gluconate (Rosenthal, Argonne)	++
	Mg gluconate (Rosenthal, Argonne)	++
	Ca gluconate (Rosenthal, Argonne)	++
	Al citrate (Rosenthal, Argonne)	++
	Th citrate (Rosenthal, Argonne)	++
	Parathyroid extract (Copp, Berkeley)(b)	0
	Parathyroid extract (Arnold, Utah)	++
For ^{91}Y on skin	Mn gluconate (Rosenthal, Argonne)	+
	Fe gluconate (Rosenthal, Argonne)	+
	Ti citrate (Rosenthal, Argonne)	++
	Mg gluconate (Rosenthal, Argonne)	0
	Na salicylate (Rosenthal, Argonne)	?
	Parathyroid extract (Copp, Berkeley)(b)	0
For ^{89}Sr and ^{90}Sr	Stable Sr (MacDonald, UCLA)	+
	A series of 32 miscellaneous agents (MacDonald, UCLA)	see text
	Stable Ca (MacDonald, UCLA)	0
	High Ca diet for 2 months (Copp, Berkeley)(b)	+
	Low P diet (Ray, University of Washington)	+++
	Rachitogenic diet + ammonium chloride (Ray, University of Washington)	++
	Diuresis induced by different agents (MacDonald, UCLA)	0
	Detergent plus epinephrine on wounded skin (Copp, Berkeley)(b)	see text

Of all of these, only a few showed marked effects in terms of increased excretion, reduced retention in bone, or both. The ratings given by Marcia Rosenthal are indicated beside the items. The three-plus rating was the highest. Obviously, some fairly heroic procedures were quite effective but would be fraught with dangers in clinical use for humans.

Of the series of thirty-two chemical agents tried by MacDonald in 1950, all of them readily available, only a few definitely decreased skeletal accumulation of

(a) For removal from bone.

(b) Copp had moved to the University of British Columbia by the time of the meeting, but it is presumed that most of the work reported was done before he left Berkeley.

orally administered strontium (either radioactive or stable). These were in order of decreasing efficiency: magnesium sulfate, sodium sulfate, ammonium amidopolyphosphate, two carboxylic-type cation exchange resins, a colloidal phosphorylated glucoside, calcium phytate, pectin, bran cereal, castor oil, and a hydrophilic laxative derived from plantain (MacDonald 1956).

Some agents actually *increased* skeletal accumulation of ingested strontium. These were: powdered milk, tannic acid, inulin, sodium alginate, and a modified starch.

The work at the University of California, Los Angeles (UCLA), with ^{90}Sr - ^{90}Y differed in outcome somewhat from that using the much larger quantities of stable strontium. The researchers at UCLA were unable to alter "more than slightly" the percentage of radiostrontium dose retained. The gloomy outlook on radiostrontium removal in these early days is clearly revealed by the summary that MacDonald gave to his paper at the Argonne meeting. It is quoted below:

We must conclude that the status of the "medical armamentarium" for treatment of radiostrontium poisoning, as a physician might put it, is truly lamentable. In our opinion, there is some hope for reducing the danger from exposure to radiostrontium via ingestion or inhalation by the maintenance of a highly positive metabolic calcium balance, *before* exposure is anticipated. If, after an incident, it is learned that radiostrontium has been inadvertently swallowed, then oral treatment with Epsom salts or sodium sulfate, for example, within the first hour, should decrease its intestinal absorption. The value of ingesting milk products while the radiostrontium is still in the stomach or gut has not been demonstrated unequivocally as yet. However, immediate intravenous injection of *moderate* quantities of stable strontium or calcium gluconates and possibly the infusion of protein hydrolysates or pectin may be of some aid.

At present, we have no agent which will lower the radiostrontium bone burden significantly, if the isotope has been in the body for more than a few hours. (MacDonald 1956).

Full reporting is contained in the paper. This was primarily in the days before chelation therapy. We have already seen that the standard chelators did relatively little for strontium removal. However, research continued on other means, much of it in European laboratories. We will consider this now.

The excellent review by Nelson from the United Kingdom (Nelson 1963) gives details of additional work with strontium, mostly with the same substances as used earlier, but adding strontium lactate, calcium chloride, and sodium and calcium lactate. All had only marginal effects. However, the same was true of chelators. Nelson's review has an excellent summary of newer work on dietary modifications, including work done at the University of Tennessee-AEC Animal Farm at Oak Ridge (chapter 13) by Comar and associates, by Palmer and associates at Hanford, Clarke and associates at Hanford, and by Cohn and associates at NRD. In addition, Nelson considers work by Catsch and collaborators at Karlsruhe and studies in France.

The additional work could hardly be said to offer great hopes from the animal experiments toward application to strontium uptake or removal in humans. Little further work was done in the United States or the United Kingdom.

Ways to reduce absorption of ingested radiostrontium were included in the 1969 general review by Bair and Smith.

A moderately early set of experiments was carried out by Volf (1963) while he was still at the Institute of Radiation Hygiene in Prague. Attempts were made to reduce the absorption of radiostrontium from the gastrointestinal tract by

barium sulfate and normal calcium phosphate administered orally to rats and humans. Phosphates increased the fecal excretion of radiostrontium, but lowered urinary excretion so that total excretion remained the same. This bespeaks some reduction in gut absorption. Sulphates increased the amount of strontium in the small intestine at early times, but later promoted urinary excretion. There was a small influence of orally administered chlorides, but this, like the other substances, was most effective when the substances were given in "sufficient concentrations," and in this case, shortly before the radiostrontium injection.

At the Second European Congress on Radiation Protection of the International Radiation Protection Association, cited earlier, work was reported on mineral sorbents for reduction of absorption of radiostrontium and radiocesium from the intestinal tract of dogs and rats (Borisov et al. 1973, USSR), decorporation of strontium with sodium alginate and some radioprotective agents (Máté et al. 1973, Hungary), and another try at zirconium therapy for ^{85}Sr and ^{144}Ce (Severa 1973, Czechoslovakia).

In the first work, adsorbents used to delay or prevent ^{85}Sr absorption (polyantimonine, KU-Z resin, sodium alginate, BaSO_4 , and "Adsobar") showed high efficiency. Polyantimonine was the most efficient and was recommended for human use. In the same work, derivatives of ferrocyanides (Berlin blue, Prussian blue, cobalt ferrocyanide, nickel ferrocyanide, all in soluble form; and insoluble Berlin blue) were tried in the case of ^{137}Cs adsorption. Highest efficiencies (above 90%) were found for the ferrocyanides.

In the second work, the objective was again retardation of absorption of strontium. In addition to strontium, the animals were given x-irradiation. The radioprotectors seemed able to complex strontium and reduce retention. The irradiation increased retention. The sodium alginate reduced retention to about 50%, the largest change seen in retention as contrasted to absorption.

Work on zirconium used soluble zirconium compounds given orally or intravenously for possible retardation of the absorption of ^{85}Sr or ^{144}Ce from the gastrointestinal tract. The percentage of injected dose of ^{144}Ce in liver was reduced from about 71% to a low of about 52%, using zirconium nitrate given intravenously. Skeletal retention was very low, about 1.1%, but the same zirconium compound reduced it to 0.7% of dose. The zirconium had essentially no effect on retention of ^{85}Sr except for zirconium citrate in a form called ZrC given by mouth. If both the radioisotope and the complexer were given simultaneously, the percentage of ^{85}Sr in tibia was reduced from 1.6% of injected dose to about 0.6%. The authors conclude that all of the investigated chemicals had a significant effect in reducing ^{144}Ce in liver and femurs, but that the change in ^{85}Sr in bone was not biologically significant.

Another approach was that used by Richmond and Furchner (1961) for removal of ^{137}Cs . They used a diuretic, "DIOMOX," in rats and found the turnover rates of two of the components of the normal cesium retention equation were increased about 20%.

Relatively recent work from Belgium (Vanderborght, Van Puymbroeck, and Babakova 1978) studied the effects of alginate administered simultaneously by two routes on the distribution and excretion of strontium deposits of long standing. The philosophy was that earlier work had indicated that sodium alginate was somehow activated by incorporation into bread. This was based in turn upon the finding of a marked increase in the concentration of radioactive strontium in blood (mice) when alginate was added to a diet containing starch. There was also some work on an ambulant human volunteer. The regimen for the

animal experiment combined alginate administered intraperitoneally, and alginate in a starchy dough made part of the diet. The concentration of ^{85}Sr in blood of the mice rose by a factor of five. About half of the mobilized strontium appeared to be available for urinary excretion, practically none for increased fecal excretion. The amounts in liver, kidney, and spleen also increased. However, the portion in bone (femur) either increased slightly or remained the same. Thus, little benefit is to be expected from these processes once the strontium is within the tissues. They seem to move the strontium around a bit but not accomplish much net decrease of body or bone burden. So much for strontium and cesium removal by nonchelator means. Some work using nonchelation methods for removal of actinides was cited in the discussion of combination therapy above. Little more needs to be said here about actinide mobilization since the results were fairly uniformly uninteresting. However, there are still a few important radionuclides that were approached by nonchelation methods and some further combinations worthy of note.

At Los Alamos, Richmond, Drake, and London (1973) demonstrated effective removal of radiorubidium by ferric ferrocyanide without interference with sodium or potassium homeostasis.

Ruthenium exposures are of considerable practical importance. As reviewed earlier in this book (e.g., chapter 9), ruthenium releases from the Hanford production facilities stimulated experimental work not only on respiratory hazards, but on possible therapeutic removal. Much of this was done at Hanford and involved the inhalation route, which we will come to presently.

The chemistry of ruthenium is so complex that predictions of the effect of chelators were not certain. However, most of them turned out to be ineffective, probably because ruthenium forms very stable complexes with proteins. Catsch and Seidl (1963) screened a number of compounds and did find one that caused a pronounced reduction in retention of ^{106}Ru in tissues. This was a long chain sulfur compound called "BATE" (for 1:2-Bis-[2-di(carboxymethyl)aminoethylthio] ethane). This is a dithiol and could be viewed as a cross between BAL and the DTPA-type compounds. The ruthenium-BATE complex left the blood much more rapidly than ^{106}Ru alone. However, the reactions of ruthenium are slow, and large differences in mobilization were difficult to obtain.

Other nonchelator approaches for various elements are fairly obvious and have been tried in most of the laboratories engaged in work on therapy of incorporated radionuclides. One which is not obvious was mentioned by Bair and Smith (1969): administration of a substance that will change the pH of the stomach to a more alkaline value and thus reduce the solubilization of the radionuclide that normally occurs in the acid environment of the stomach.

With liver engaging almost as much attention as bone as a deposition site for plutonium, some interesting combination therapies have been tried. One (Rosenthal et al. 1973) used glucan, the polysaccharide derived from the cell walls of baker's yeast. It was postulated to foster disruption of intracellular aggregates of plutonium that characteristically form in liver. The work involved mice and trials of glucan alone, DTPA alone, and the two combined. Forty-seven days after administration, net removal of plutonium from the liver was 8.5% with glucan, 11.5% with DTPA, and 19.5% with combined therapy. The mobilization from liver was considered to be at least partly accomplished by intracellular penetration and action of the glucan, which brought the plutonium out where it could become available to the DTPA.

Some of this work involves trials on man without extensive testing on animals. We will review these in section V.

A considerable effort in animal experiments has been directed toward decontamination procedures for wounds and skin. These involve both chelation and nonchelation methods. Bair and Smith at PNL (1969) give an in-depth review of the processes involved in skin absorption, including a useful review of the anatomy and physiology of skin, the rate of penetration of many substances through skin, and the influence of injury by wounds or burns thereon. They give an interesting review of work by investigators at NRD (Loeffler and Herron 1951) in which it is shown that the vasoconstrictor, epinephrine, can markedly reduce the absorption of radiostrontium in rats. They also discuss French work using iontophoresis for removing radioelements from skin (Michon 1956) and ultrasonic methods for the same in work at Hanford (Neef and Ballou 1957).

The above potpourri of agents and methodologies is hardly amenable to summarization. It does demonstrate that few logical stones have been left unturned in the quest for therapy of deposited radionuclides. The animal work contributed many important pieces of information, both encouraging and discouraging. It formed the basis for decisions regarding therapeutic procedures to apply to man—many of which stood the test of clinical trial. A few routines have been established out of all of this. This culmination of the extensive and frequently discouraging animal work will be apparent in section V.

F. Therapy for Inhaled Radionuclides

The number of animal experiments on removal of radionuclides deposited in the body by inhalation is not in proportion to the importance of the inhalation route of intake. This may be because the large efforts toward decorporation of stable metals had already fixed upon other routes, or it may have been because of the technical difficulty of inhalation experiments with radioactive materials.

Major studies of therapeutic removal of inhaled radionuclides did take place at two of the U.S. laboratories deeply engaged in pulmonary radiotoxicology: Hanford's Pacific Northwest Laboratory in Richland, Washington, and the Lovelace Inhalation Toxicology Research Institute in Albuquerque, New Mexico. The work began first at Hanford and was quite general in scope. The work at Lovelace began considerably later (the laboratory was not in existence, of course, when the work began at Hanford). There was also good work in several European laboratories.

The Hanford efforts began in the 1950s, but the published reports began in the 1960s. Tombropoulos and Bair (1962) led off with a study of the removal of inhaled ^{144}Ce – ^{144}Pr from rats. They tried phenylephrine hydrochloride with or without DTPA, DTPA alone, and the detergent "Pluronic F68." There were two experiments, one terminated twenty-one days after exposure, the other fifteen days after exposure. Retention in liver and lung was very significantly reduced, particularly when treatment was started as soon as one hour after exposure. The DTPA appeared to be the prime agent. The investigators were greatly encouraged toward removal of other insoluble radionuclides from the lungs.

However, in the next year, the Hanford group (Tombropoulos, Bair, and Park 1963) had to report that neither DTPA nor "Pluronic" was very effective in removing $^{239}\text{PuO}_2$. Yet, the importance of removing plutonium and similar insoluble actinides stimulated hundreds of further trials both in the United States

and Europe. Work was reported in dogs a few years later (Tombropoulos, Bair, and Park 1969).

Results were summarized in the IAEA symposium, Diagnosis and Treatment of Radioactive Poisoning (see Bair, Tombropoulos, and Park 1963) and at the Hanford symposium, Inhaled Radioactive Particles and Gases, held in May 1964. At that meeting, Tombropoulos (1964) presented a review of the many therapeutic procedures (not only chelators) for removal of inhaled radionuclides applied in animal experiments. The bulk of the work had been done at Hanford, although researchers from a few other laboratories had contributed (e.g., Charles LaBelle who had moved fairly recently from Rochester to Jefferson Medical College in Philadelphia to work in the active pulmonary toxicology center headed by H. Brieger).

1. Physiological Approaches

Early approaches to therapeutic removal of radionuclides from the lungs were directed toward stimulation of lung clearance by stimulation of phagocytosis and of mucus-transport, application of bronchodilators, application of substances which reduce the tenacity and viscosity of pulmonary secretions (surfactants), and combinations of these.

Harking back to the phenomenon examined in chapter 9 that pulmonary clearance rate frequently increased when the deposited mass increased, LaBelle and Brieger (1960) and LaBelle, Bevilacqua, and Brieger (1964) tried adding "inert" agents to increase the mass deposited in lung, hoping thereby to increase clearance rates and thus sweep out some of the deposited radioactivity. They tried carbon, sand, asbestos, silica gel, and aluminum hydrate. The carbon (from India ink) had the greatest effect. The lung burden was reduced to 30% of the control using silver iodide (Ag^{131}I) as the radioactive material.

Unfortunately, workers in other laboratories, primarily Hanford, could not obtain such a large effect for other radionuclides, e.g., $^{144}\text{CeO}_2$, $^{59}\text{Fe}_2\text{O}_3$, $^{239}\text{PuO}_2$, and $^{106}\text{RuO}_2$. In fact, the lung burdens were sometimes increased. The work is described in the review by Bair and Smith; some of the data are shown in table 19.13, modified from Bair and Smith.

TABLE 19.13. Effect of Phagocytic Stimulating Agents on Removal of Radioactive Particles from the Lung

Radioactive Particle Inhaled	Test Agent	Method of Admin.	Duration of Test (days)	Lung Burden (% control)	References
Ag^{131}I *	Carbon (Peerless Mk17—channel black)	aerosol	1+	30	LaBelle, Bevilacqua, and Brieger (1964)
$^{144}\text{CeO}_2$ †	Carbon (India ink) > 1 mg deposited in lungs	aerosol	7	110	Bair and Hennacy (1962)
$^{59}\text{Fe}_2\text{O}_3$ †	Carbon (India ink) > 1 mg deposited in lungs	aerosol	21	110	Bair and Dilley (1966)
$^{239}\text{PuO}_2$ †	Globulin + pluronics F-68 + DTPA + hyaluronidase	aerosol	21	120	Tombropoulos, et al. (1964)
$^{106}\text{RuO}_2$ †	Choline	aerosol	7	110	Willard (1966)

* Given by intratracheal injection to rabbits.

† Inhaled by rats.

Note that the test agent included substances other than carbon, sometimes mixtures, and that the test agent was inhaled, as was the radionuclide, but not along with it.

An extensive cadre of parasympathetic drugs, mucolytic and surface active agents was tried for removal of ^{106}Ru , ^{144}Ce , ^{239}Pu , and ^{59}Fe . The results are shown in detail in the review by Bair and Smith, with the experimental work coming again primarily from Hanford. There was little consistent effect on lung clearance. Bronchodilators (e.g., phenylephrine HCl, Isuprel) showed slight effectiveness, mucolytic agents (Alevaire, Dornovac [desoxy ribonuclease] and Aerosol TR), and surface-active agents (Pluronic F-68, Triton, Tween-80) were essentially without effect except for an experiment on plutonium removal quoted below. Pulmonary irritants appeared to hasten removal of some insoluble oxides (e.g., $^{106}\text{RuO}_2$) from rats, but the results were inconsistent and difficult to substantiate. Also, the purposeful administration of pulmonary irritants to humans would require clearly life-threatening deposits of radioactivity and marked increases in clearance.

The results with expectorants (Terpin hydrate, sodium iodide, Isoprel plus ammonium chloride, Alevaire plus ammonium chloride) were likewise of marginal benefit or even made things worse.

Complicating all of this was the influence of the physical state of the inhaled agent as well as its chemical form. The only generalization that Tombropoulos could draw regarding physiological means for hastening removal from the lung was that agents that decreased mucus secretion showed some promise of expediting clearance, while agents that increased mucus secretion tended to increase retention. Apparently, the considerable reduction of Ag^{131}I burden in the lung by carbon particles shown in the work of LaBelle et al., the largest effect seen (table 19.13), was idiosyncratic.^(a)

It should be added that although most of the test administrations in the Hanford work utilized aerosols of the therapeutic agent, for reasons we will examine presently, use of intraperitoneal or other parenteral routes did not alter the picture appreciably.

The normal pulmonary clearance process is one of nature's most efficient mechanisms. It is not really surprising that we could not do much to improve upon it in normal subjects. Unfortunately, we do not have information for situations where clearance was not normal. The effect of these various physiological manipulations might be of more importance in the presence of the types of pulmonary pathology where clearance is abnormally slow. Thus, the above work is primarily applicable to healthy workers. It might or might not apply verbatim to general populations with their complement of emphysemics, etc. Future research might profitably be directed toward this facet.

2. Complexing Agents

Even while the physiological means were being investigated, chelating agents of the EDTA, DTPA type were added to some of the mixtures (see, for example, the work with $^{239}\text{PuO}_2$ in table 19.13). However, the enhancement factors for these mixtures were not promising.

(a) LaBelle introduced the radioactive material by intratracheal instillation rather than by inhalation. Since no work was done using inhaled Ag^{131}I , we cannot determine whether it was the technique that accounted for the difference.

Somewhat more encouraging results were seen in experiments of Schmidtke (1964) reported at the Hanford symposium, Inhaled Radioactive Particles and Gases. She tried having guinea pigs inhale a fog of a 25% DTPA solution and also gave daily subcutaneous injections for one week. This regimen produced a significant increase in clearance of ^{91}Y from the lungs and more rapid excretion in the urine. However, Hanford studies with inhaled plutonium, done well before the cited symposium (Tombropoulos, Bair, and Park 1963) indicated that neither DTPA nor TTHA had much effect on removal of this radionuclide from the lungs.

Further work turned to a variety of radionuclides, some of which is shown in table 19.14, modified from the review of Bair and Smith.

TABLE 19.14. Effect of Chelating Agents on Removal of Inhaled Radionuclides

Radionuclide Compound	Test Agent	Animal Species	Treatment Method	Duration of Test (days)	Lung Burden (% control)
$^{91}\text{YCl}_3$	DTPA	guinea pigs	aerosol immed. after exposure, subcut. daily	8	2
$^{91}\text{YCl}_3$	Hexameta-phosphate	mice	aerosol—9 treat. begin immed. after exposure	15	40*
$^{239}\text{PuO}_2$	DTPA + Pluronic F-68	rats	aerosol	29	120
$^{239}\text{Pu}(\text{NO}_3)_4$	Diethyldithio-carbamate	rats	subcutaneous injection	40	110
	TTHA			40	71
	DTPA			40	89
$^{106}\text{RuO}_2$	EDTA	rats	aerosol	14	120
	TTHA			14	130
	DTPA			14	120
$^{144}\text{CeO}_2$	DTPA	rats	aerosol—beginning 1 hr after exposure†	21	7
	DTPA		aerosol—beginning 24 hr after exposure	21	23
	DTPA		aerosol—beginning 1 hr after exposure	15	11
	DTPA		aerosol—beginning 24 hr after exposure	15	31

* Estimated from histograms in author's paper.

† I.P. administered DTPA was also effective.

All of the work quoted is from Hanford except the work with $^{91}\text{YCl}_3$, which was done by Schmidtke in Freiberg and Gensicke and Nitschke (1964) in Berlin. Obviously, plutonium and ruthenium were much more tenaciously held in lung than yttrium or cerium and were much more difficult to mobilize. If the cerium was calcined before inhalation, removal of it became more difficult. This is illustrated in figure 19.11. Thus, solubility of the inhaled material can be a controlling factor as would be expected.

FIGURE 19.11. Effect of DTPA treatment on removal of inhaled $^{144}\text{CeO}_2$ in rats. Rats were exposed daily for 30 min to aerosols produced from 25% DTPA and sacrificed after 3 wks. Data are means of 6-12 rats. (Redrawn from Tombropoulos and Bair, cited in Bair and Smith 1969. Reprinted with permission of Pergamon Press, Elmsford, New York, copyright 1969.)

Because of the importance of finding a good therapeutic regimen for inhaled insoluble^(a) plutonium, additional animal work was done, both at Hanford and at Lovelace. Schmidtke's work, in Europe, had already shown that chelators like DTPA were rapidly absorbed from the lung. Because of the convenience of self-administration from an atomizer, some of the work aimed at clinical uses of the therapeutic agents in the form of inhaled aerosols. In fact, the inhalation route did seem to confer some additional effectiveness to the therapeutic agent (Bair et al. 1973). It appeared that most of the increased removal came from lung and liver, little from deposits in bone.

Annual reports from the Hanford laboratories in the late 1950s, and those of its successor organizations, contain continuing references to work on the removal of inhaled plutonium as well as other actinides, particularly americium. It also extended to species other than rodents. While we laud this dogged persistence, there seems little need to detail the results, since there were no major improvements in the overall effectiveness of the *chelators alone*.

An illustration of the nuances of plutonium removal as seen in Hanford work is shown in figure 19.12A and B. Figure 19.12A shows that treatment of dogs with the detergent "Pluronic" yielded greater fecal and urinary excretion from deposits of $^{239}\text{PuO}_2$ than did DTPA. Figure 19.12B illustrates the rather miserable amount of reduction in body burden of inhaled plutonium in rats by a number of chelating agents.

Work at the Lovelace Foundation Inhalation Toxicology Research Institute (see chapter 9) concentrated largely on pulmonary lavage in combination with

(a) Soluble forms, of course, proceed to tissues such as bone or liver rather quickly, and removal can be approached by the methods described in earlier sections of this chapter.

chelators (see next section), but they did some work with intravenously administered DTPA for the removal of inhaled materials (e.g., Pfeleger et al. 1972a,b). Very significant reductions were noted in the content of lung, liver, and skeleton after twenty-eight days when DTPA was given one hour after inhalation. As always, there was less effect if the DTPA was applied later, but even with a five-day delay, lung content was reduced by 50%. There was, however, little reduction of liver and skeletal burdens with the delayed treatment. Urinary excretion was likewise much less affected by the late treatment.

This work points up a fairly common way in which removal of inhaled radionuclides sometimes differs from that for other routes of entry. Some substances appear to become fixed in lung with almost the same speed as in bone. Other substances seem to go through a phase in which the deposit in lung is more mobile than deposits in tissues like skeleton. Thus, while speed of attack for therapy is mandatory for some substances, e.g., plutonium, others give more chances for useful mobilization from lung. This has an important corollary. Many investigators have been concerned that uncritical application of chelation therapy might move substances from lung to a less accessible site such as bone instead of allowing the lung's natural clearance processes to operate to their maximum initially.

An interestingly different approach was tried by other investigators at Lovelace (Thomas, Scott, and Thomas 1969; Thomas and Chiffelle 1974). Zymosan, obtained from yeast, was known to stimulate reticuloendothelial cell proliferation. It was reasoned that such stimulation of reticuloendothelial system function in the lung might hasten phagocytic removal of particulate material. There were changes in several respiratory parameters, but an increase in net clearance of ^{137}Cs in fused clay did not occur. The work gave more information on clearance kinetics and mechanisms than therapeutic promise.

3. Lung Lavage

The procedure of washing out deposits of unwanted material from the lungs, while hardly commonplace, has become firmly established in the medical management of pulmonary obstructive diseases. Application of pulmonary lavage to the removal of radionuclides occurred in several laboratories, primarily around potential clinical needs. In 1968 and 1969, Sanders, at Hanford, demonstrated removal of $^{239}\text{PuO}_2$ particles by lavage of excised rat lungs (Sanders and Adey 1968, Sanders 1969). This was quickly followed by work with living animals at Lovelace (Pfeleger, Wilson, and McClellan 1969; Pfeleger et al. 1969). In this work, ^{137}Cs in fused aluminosilicate was used. Work with lavage also began in laboratories in Europe, particularly France.

Since pulmonary lavage is hardly an everyday happening, a short review of the procedure seems in order. The one used for beagles, and closely similar to that used for man, is described carefully by Muggenburg, Felicetti, and Silbaugh (1977). It is excerpted below:

Briefly, the procedure was to anesthetize the patient with a mixture of halothane, nitrous oxide and oxygen and place a Carlen's double lumen bronchosprometry tube in the trachea to provide functional separation of the right and left lungs. Using the anaesthetic gas mixture, nitrogen was washed out of the lungs and the airway tube to the lung to be lavaged was clamped. While ventilation was maintained in the other lung, isotonic saline was slowly introduced into the lung until a volume equal to the functional residual capacity of that lung was reached.

Additional volumes, approximately tidal volumes, were then added and drained repeatedly. Finally, all the fluid was drained and ventilation was reestablished.

Another lavage procedure has also been used experimentally in beagle dogs to remove inhaled radioactive particles and to treat chronic obstructive lung disease in children. In this procedure, a single lumen endotracheal tube was placed in the trachea after induction of anaesthesia. The patient was placed in a position so that the lung to be lavaged was down [i.e., in the down side, so that fluid would travel into it]. After placement of the endotracheal tube, the patient was hyperventilated to lower arterial carbon dioxide tension to induce a state of temporary apnea. During apnea, isotonic saline was introduced into the lung by gravity. The volume of fluid used approximated the total lung capacity for the lavaged lung. The fluid was then drained and the cycle of hyperventilation, introduction of fluid and drainage of the fluid was repeated until completion of the desired number of washes. (Muggenburg, Felicetti, and Silbaugh 1977, references omitted)

Experimental procedures used in small rodents range from variations of the above to surgical removal of the lavaged lung and draining of the contents into a suitable receptacle for counting.

The Lovelace group extended their work to baboons and to one human who accidentally inhaled ^{239}Pu (see section V).

From initial success with relatively mobile $^{137}\text{CsO}_2$ to less mobile ^{137}Cs in fused aluminosilicate, they extended to ^{95}Zr - ^{95}Nb , $^{144}\text{CeCl}_3$, ^{144}Ce in fused aluminosilicate, ^{238}Pu and ^{239}Pu oxide particles, and ^{241}Am oxide particles. Lavage was equally effective in removing these particles from the lung. However, multiple lavages were needed (the Lovelace group used ten) to attain really significant removals, e.g., 40% to 44% of the initial lung burden. Furthermore, it was found that lavage was not very effective for material of short retention time. Indeed, it appeared that it might be better to leave such deposits alone, for the lavage procedure can interfere with normal clearance processes and is not needed anyway for short half-life materials. On the other hand, for some of the more tenaciously held substances, lavage seemed to be the only effective removal method available.

Illustrative of the results at Lovelace and of special interest because it involves the use of "real world" aerosols of mixed oxides is the information shown in table 19.15. The removal from lung is striking. Changes in excreta and in other tissues are not so striking and are sometimes in the wrong direction, though not significantly so.

Lavage with a DTPA solution in contrast to lavage with saline increased the effectiveness; at least for the removal of ^{144}Ce . (Pfleger et al. 1972a,b; Muggenburg et al. 1972) and probably for the other radionuclides tried.

An important feature of the experimental work with lung lavage was the finding that the time of initiation of treatment was not critical up to several months after exposure. The incremental efficiency of lavage seems to fall off with time when a series is given at relatively short intervals, e.g., two days. By contrast, a sometimes surprisingly large new increment can be mobilized when lavage is resumed after a considerable period without treatment.

Much attention was devoted in the Lovelace work to the hazards of lavage. It is not a totally innocuous procedure, as we will see in section VI. However, on the basis of the fairly extensive animal experience, a recommended procedure for humans was worked out. Careful evaluation is needed in each individual case.

Somewhat surprisingly, and in some contradiction to the precautions emphasized above, the French have reported ability to lavage *both* lungs at the same

TABLE 19.15. Plutonium Activity in the Feces, Urine, Lavage Fluid and Tissues of Beagle Dogs^(a) Exposed by Inhalation to Industrially Produced Mixed Oxides of Plutonium and Uranium and Subsequently Treated with Lung Lavage and DTPA.^(b)

(b) Treatment consisted of ten lung lavages and eighteen intravenous injections of DTPA.

Source: Modified from Muggenburg et al. 1979.

sitting, in baboons at least (Nolibé et al. 1977). All U.S. practices have employed only one lung at a time and even then with a two-day interval between treatments. Thus, any given lung received lavage at intervals of no less than four days. One reason for the urgency felt by the French workers was their finding that ²³⁹PuO₂ produced early lung pathology in baboons at lung burdens a factor of three lower than in dogs or rodents (Metivier et al. 1974). If applicable to humans, obviously the technique could accomplish more rapid removal, but it requires very careful standardization with provisions for individual variations as described in detail by Nolibé et al. (1977). The decision to use bilateral lavage would presumably rest upon the demonstrated presence of truly dangerous quantities of a dangerous radionuclide. This statement is made despite the conclusion of the French workers that the main medical risk of lavage is associated with repeated anesthesia of the subject.

A modicum of work has been done to prove reduction of biological effects of inhaled radionuclides by virtue of lavage procedures. The Lovelace group contributed most to U.S. work on this facet (Boecker et al. 1974; Muggenburg and Mauderly 1975; Silbaugh et al. 1975). The work summarized in the 1977 review by Muggenburg used dogs exposed to aerosols of ¹⁴⁴Ce in fused aluminosilicate particles. They studied the survival time, incidence, and severity of radiation pneumonitis, and any other relatively early pathological changes. There was no doubt about the effectiveness of the treatment in terms of early effects, i.e., less pneumonitis, longer survival. The French work already cited included studies of pathology, but it was directed more toward effects of the lavage treatment than effects of the deposited radionuclide. They did show significant increases in the survival time of the treated animals.

We will now review experience, both experimental and clinical, in humans and close with a review of the pharmacology and toxicology of the main-line chelators.

V. Experience in Man

Experience concerning the therapeutic removal of radionuclides from the human body has been gained both as part of experimental investigations at the tracer level and as a result of clinical situations resulting from accidental intakes. Frequently, the information on therapy was part of more general studies of the metabolism of radionuclides in man. We will review this experimental work first.

A. Experimental Studies

The bulk of this type of work in the United States was done in the laboratories and metabolism ward of Dr. Herta Spencer and her many colleagues at the U.S. Veterans Administration Hospital in Hines, Illinois. Initial work was done at the Montefiore Hospital in New York, where Dr. Spencer was a collaborator (and wife) to Dr. Daniel Laszlo in the Division of Neoplastic Diseases until his death in June 1958. A few years later, she moved to the Hines facility and has made a full career of these studies. There were occasional collaborators from other organizations, e.g., the AEC's Health and Safety Laboratory in New York. Except for needed technical and nursing assistance, this work represents largely the efforts of the principal investigator. It required the facilities of a major metabolism ward and the large professional and technical staff always associated with these operations.^(a)

The work concentrated mostly on strontium, since a convenient short half-life isotope was available (^{85}Sr), and the work began in the midst of the agitation to gain all possible knowledge about the principal radionuclides in fallout (chapter 13).

The first report of broad scope came at the Argonne symposium, Therapy of Radioelement Poisoning, held in 1955. Laszlo and Spencer (1956) gave an overview of effects of Na-EDTA and Ca-EDTA on urinary calcium excretion, including radiocalcium; distribution of lanthanum when injected as the chloride or in chelate form (versenate); influence of EDTA on urinary excretion of the lanthanum-140-EDTA complex (marked increase); and the effect of calcium level on urinary excretion and plasma levels of ^{85}Sr . The findings presaged those to be taken up presently. All work involved patients, but their clinical conditions were quite disparate.

At the second Atoms for Peace Conference in Geneva, Switzerland, Laszlo and Spencer (1959) presented a summary paper on radiostrontium metabolism and decontamination in man. The work was done at the Montefiore Hospital, and it references a long series of detailed individual publications beginning in the 1950s.

(a) Some of the patients were essentially volunteers whose presence in the hospital was adventitious to the study, others were patients with advanced neoplastic disease, especially with bone metastases, as described in the many publications. In all cases, the radionuclide doses were strictly at the tracer level.

Calcium intake and variations in the calcium status of the body were found to have effects on the metabolism of strontium in man just as in animals and as they had earlier been found for radium (chapter 1). Absorption of ingested tracer strontium remained in the same range whether the calcium intake was high or low. However, it appeared that any situation that enhanced calcium excretion also enhanced strontium excretion. Indeed, there was somewhat greater enhancement of the strontium loss. Addition of ammonium chloride to produce acidosis caused enhancement of urinary ^{85}Sr excretion, but it was not as large as that caused by calcium gluconate. The two treatments together caused a further enhancement, which was roughly additive. Calculated body burdens of ^{85}Sr were clearly reduced. Of special interest was the fact that oral administration of ammonium chloride was effective in removing radiostrontium as late as fifteen days after exposure. This interaction of calcium and strontium led to a study of twenty adults who received simultaneously tracer levels of ^{85}Sr and ^{45}Ca , given orally. More calcium was absorbed, more absorbed radiostrontium was excreted via the kidney. (For more on this discrimination between calcium and strontium see chapter 13.)

Laszlo and Spencer (1956) also give data on ^{85}Sr content of bone with and without metastases (osteolytic metastases) from some of the patients who were in advanced stages of neoplastic disease. Also the effects of sodium-EDTA were reported in this summary. They were just as negative in this work in man as the animal work had predicted.

The strontium work in man was further described by Spencer and Laszlo (1960) in the book on metal binding edited by Seven and Johnson. The report reiterated the substance of the Geneva paper but gives more information on the clinical state of the patients and its possible influence on strontium excretion. Most of the studies were carried out with low calcium diets. Both urinary calcium and urinary strontium were lowest on a low calcium diet. They were higher on a high calcium diet and highest on a high calcium diet plus ammonium chloride. In this work, Na_2EDTA decreased urinary ^{85}Sr excretion. There was a compensatory increase in excretion after cessation of the chelator treatment.

At the 1962 IAEA symposium, which we have already quoted in many other connections, Spencer has a further review of the removal of radiostrontium from man (Spencer 1963).^(a) There was expansion of the routes and mixes of calcium gluconate and ammonium chloride; addition of the more effective chelator, Ca-BAETA , which we met in the review of the animal experiments; and the influence of stable strontium was compared to stable calcium. The newer chelator, BAETA, was indeed more effective as presaged by the animal experiments. Stable strontium appeared to be more effective than stable calcium in producing a carrier effect. Work published in 1965 in collaboration with investigators from the New York Health and Safety Laboratories of AEC (Spencer et al. 1965) further extended these findings.

In still later work, Spencer and her colleagues included agents that might influence the gut absorption of strontium. In 1968 a news release from the National Center for Radiological Health of the U.S. Public Health Service (HEW-T-4, dated 26 January 1968) espoused the use of aluminum phosphate gel to

(a) This and all subsequent work came from the Hines Veterans Administration Hospital.

inhibit gastrointestinal absorption of strontium. This was based on work done at Hines. It was published in the *International Journal of Applied Radiation and Isotopes* and in *Radiation Research*. It is summarized in what appears to be the last major paper on strontium in man from this group, viz., in the AEC-sponsored symposium on Biomedical Implications of Radiostrontium Exposure, held at Davis, California, in 1971 (Spencer, Kramer, and Samachson 1972). The added isotope was ^{85}Sr as before. The intestinal absorption was calculated from fecal excretion and also from the blood plasma level. In addition, technology had advanced to the point where the ^{90}Sr in the diet, urine, and feces could be determined by low-level beta counting without addition of any exogenous isotope. This may be important if the form of the element in food or body fluids is a complex different from that present at early times or is in some other way altered so that solubility might be changed. These studies with ^{90}Sr were complete balance studies.

There was confirmation and expansion of the earlier work on diet, ammonium chloride with and without chelators, plus gastrointestinal absorption work using vitamin D, lactose, lysine, parathyroid extract (no effect with any of these),^(a) and aluminum phosphate gel (marked decrease in ^{85}Sr absorption). Diuretics were variable in action. Those that did increase urinary excretion of strontium accomplished no net gain since there was a compensatory inhibition of excretion later. Intravenous stable strontium and magnesium had small but definite effects toward increasing excretion. The newer chelating agent BAETA proved the most effective of all the measures taken.

On balance, this laboratory work on man demonstrated that "something could be done" about strontium uptake and removal even though it was not comparable to the more dramatic results (in a relative sense) with plutonium and other actinides. The procedures are hardly simple, nor do they remove large quantities of deposited strontium. The efforts to decrease gastrointestinal uptake that looked promising did not immediately become part of the recommended routine clinical management practices. However, the message seems to have gotten across, for recent (NCRP 1980) summaries of recommended actions include administration of aluminum phosphate immediately in cases of strontium contamination.

Spencer's laboratory was engaged in very broad studies of the metabolism of metals in man. She did not by any measure limit her efforts to strontium. The rare earth elements came in for extensive experimental work (Rosoff et al. 1961; Spencer and Rosoff 1963). Lanthanum, yttrium, and scandium (^{140}La , ^{90}Y , and ^{46}Sc) were administered intravenously in either ionic or chelated form.^(b) Urinary excretion was low for the ionic forms, almost quantitatively complete in twenty-four hours for chelates. Gut absorption of the ionic forms was almost zero. Blood studies showed binding to various globulin fractions by lanthanum and scandium, but no binding at all by yttrium. The chelating agents of the EDTA-DTPA type were quite effective in removal of tracer doses of rare earths, with DTPA the more effective. There was a relationship between urinary

(a) While parathyroid extract did not materially affect absorption, the status of the thyroid and parathyroid glands did have a marked influence.

(b) Some of the earliest work was presented by Laszlo at the Oak Ridge symposium on the rare earths discussed in chapter 4. It did not concern removal techniques, just the basic metabolic behavior.

excretion (of yttrium in this case) and the stability constant of the chelates with yttrium, much as we saw in the animal work.

Tissue distribution data in man are given in these reports, but there is no indication of how the measurements were made. Since they are expressed as percentage of dose per unit wet weight of tissue, it is presumed that there were either autopsy results or collections from surgical excisions. As expected from the animal work, these rare earth elements were sequestered in components of the reticuloendothelial system to a large degree. This may help account for their relatively ready availability for removal by chelators. Very significant removals were possible.

In a study devoted to scandium alone (Spencer and Rosoff 1965) and another to ^{65}Zn in man (Spencer and Rosoff 1966), relatively easy removal by standard and special chelating agents (zinc study) was demonstrated.

These successes led the Hines group to a degree of optimism concerning potential means for removing many of the fission products from the human body in the event of contamination. The work on therapy in toto plus many detailed experiments on the way in which man handles a variety of radionuclides of importance to contamination by fallout or other means reflects a laudable determination and constancy of purpose on the part of the principal investigator and unusual continuity of financial support from organizations that undoubtedly had many other demands on their resources.^(a)

There has been nothing else in U.S. laboratories comparable to Herta Spencer's series. However, there have been a few more or less isolated studies with volunteers. One concerned the behavior of promethium, a prominent component of radioactive waste. The work was done at Hanford by Palmer and Nelson (1970).

The isotope of concern is ^{147}Pm , but this is a very low-energy beta emitter which cannot be determined in humans except by measuring amounts excreted. Palmer and Nelson decided to harden up the excretion model for promethium by use of ^{143}Pm , which has a half-life of about 13.5 days and beta energy compatible with the use of whole-body counting techniques. Six volunteers were injected with $0.1 \mu\text{Ci}$ of $^{243}\text{PmCl}_3$, and metabolic parameters were studied for one year. DTPA was studied in eight volunteers. A marked effect of time after injection of the radionuclide appeared. Removal went from 90%, to 25%, to 5% with administrations at thirty minutes, twenty-four hours, and eighty days after the injection, respectively. This applied to urinary excretion. Fecal excretion was more or less constant with time and independent of the time interval between ^{143}Pm and DTPA administration.

There have been a few investigations using volunteers or adventitious patients in European laboratories. These focused mainly on the basic metabolic behavior of the radionuclides in man and did not engage so much in work on therapeutic removal. There are, however, a few exceptions, as described below.

Volf, while he was still at Prague, carried out studies on radiostrontium decorporation in several cancer patients (Volf 1963). This was part of a study built around animal experiments and two inhalation accidents. He studied the effect of orally administered barium sulfate on the turnover of administered radiostrontium (^{85}Sr). Urinary excretion of ingested strontium decreased several-fold following barium sulfate treatment, while there was an increase in the

(a) A large number of individual papers giving detailed results could not be referenced herein. They can be found in the bibliographies of the review-type papers cited.

amount in feces. Volf concluded that the effect of the barium was to reduce absorption of strontium from the gastrointestinal tract.

There was also considerable interest in European laboratories and some in the United States in the use in man of alginates, jelly-like substances obtained from sea kelp, as mentioned briefly in consideration of the animal experiments. Alginates effectively reduce gut absorption of many radionuclides. Experimental work by the U.S. Public Health Service (Stara and Waldron-Edward 1968) showed considerable promise for this agent in cats. However, these compounds tend to have high viscosity, tend to be difficult to ingest, and are not very readily available in the United States. For this reason, clinical protocols for the United States indicate a preference for aluminum phosphates, but European practice has continued to emphasize alginates for prevention of strontium absorption.

The metabolic data from these several experiments with man indicate that more strontium is handled in urine and excreted via the kidneys in man than is the case with most laboratory animals, an important generalization.

Some of the European work on Prussian blue included studies on man. (There was animal work on both sides of the Atlantic.) This substance (potassium ferri ferrocyanide) has been found effective in removing cesium, thallium, and rubidium, at least.

An example, using cesium, is seen in work from Karlsruhe and Norsk Hydro's Institute of Cancer Research by Madshus et al. (1966). Two of the authors took 1 μ Ci of carrier-free ^{137}Cs and initiated treatment with Prussian blue ten months later. The biological half-time was reduced from about 110 to 115 days to about 40 days. Parallel animal work showed little dependence upon treatment schedule. Since Prussian blue is not recognized in the U.S. Pharmacopoeia, nor approved by the Food and Drug Administration, any use for therapy in humans in the United States must be considered as a special emergency measure.

Further detail on this and many other drugs outside of the mainstream of the research we are reviewing can be found in the enormously useful report from the U.S. National Council on Radiation Protection and Measurements (NCRP) entitled *Management of Persons Accidentally Contaminated with Radionuclides* (NCRP 1980).^(a)

Because of the lack of suitable isotopes in the actinide series for conducting safe experimental work at the tracer level, there has been essentially no experimental work in humans with these elements, except for studies around body burdens received occupationally, idiopathically, or in nonoccupational accidents.

The general agreement between the results of animal work and the experiments with normal humans outlined in this section is much greater than might be expected.

(a) The Scientific Committee preparing this report reads like a partial "Who's Who" of American workers in the field of radionuclide therapy: George L. Voelz, Los Alamos, Chairman; H. David Bruner, formerly USAEC and DOE, Bonita Springs, Florida; Victor H. Smith, Hanford; Herta Spencer, Hines V.A. Hospital; Niel Wald, Pittsburgh; John W. Healy, Los Alamos (consultant). By the time of this activity, Harry Foreman, Bill Bair, and Jack Schubert had gone on to other things and were not automatically included as they would have been if the report had been prepared earlier. "Dag" Norwood, Hanford, had retired, or he would have been included also.

B. Accidental Exposures—Clinical Management

1. Overview

This book concerns research and the results of research. Many excellent compendia exist on the handling of radiation accidents. The nuances of clinical management will not be expanded upon here (see, for example, the recent report of the NCRP [1980] and the earlier review by Foreman [1963]). Our purpose is to examine the ways in which the extensive research findings can and have been applied to unplanned intakes of radionuclides by humans and the extent to which these clinical experiences confirm, refute, or extend the basic research findings.^(a)

Before considering specifics, the reader is reminded again that the subject of this section is but a specialized part of an important area of clinical toxicology and research on the role of metals in biomedical phenomena. We will bypass many more or less commonplace sources of potential exposure and therapy thereof (e.g., lead and mercury) since these have been considered extensively in other connections. Also, the use of sodium iodide to block uptake of radioiodine (see NCRP 1977; *Federal Register* 1978; Eisenbud 1973; and earlier chapters) requires no further exposition here.

Accidental contamination of humans with radionuclides is far from commonplace, especially if the number of potential opportunities for exposure is considered. The potential damage is serious enough, however, that every major installation handling amounts of radioactivity above certain prescribed amounts has a room set aside for possible decontamination procedures and personnel available or on call with at least rudimentary training in the applicable techniques. This frequently includes local police and fire personnel. The most informative cases from the scientific standpoint have occurred where well-trained physicians with research interests in the subject and associated laboratory facilities and personnel were either on hand or brought into the case. The industrial medical department of every major nuclear installation has for many years had chelating agents ready for possible emergency use.

The report of the NCRP, already cited, covers the subject of management of contaminated persons in considerable depth and should be consulted for specific guidance. The table of contents^(b) is reproduced below for the assistance of the reader:

- Preface
- 1. Introduction

APPENDIX A—Radiological Assistance Plan (RAP)

APPENDIX B—Definitions

References

(NCRP 1980)

The treatise on treatment of incorporated transuranic elements by Volf (1978) lists fifty-four separate incidents^(a) of actinide contamination that came to treatment with chelating agents. These extended from 1963 to 1973 and concerned only plutonium and americium, with two instances involving curium (see table on pages 1661 through 1664). At about the same time, Dolphin (1976) reviewed DTPA and its use in sixteen cases of therapy in humans for plutonium contamination in the United Kingdom and the United States. In both instances, there are many more cases of contamination via wounds than by inhalation or ingestion. In 1964, Piltingsrud reported that the Rocky Flats Plant near Denver, Colorado, operated by Dow Chemical Company and a prime handler of

(a) The numbering refers to incidents not cases. In some incidents, there were several cases and more than one publication on treatment.

plutonium, as we saw in earlier chapters, had had 1,159 wounds in the period since June 1957. About 30% of these were positive for contamination, albeit mostly at low levels.^(a) A summary of Hanford experience with plutonium over the period 1946 to 1967, with an update to 1971, is given by H. M. Parker (1973). It is shown in modified form as table 19.16.

TABLE 19.16. Summary of Hanford Experience With Plutonium

	From 1946 To 1967	Updated To 1971
Injury cases potentially contaminated	230	310
Cases containing measurable plutonium	136	162
Cases surgically decontaminated	86	100
Deposition above 5% MPBB	15	16
Deposition above 50% MPBB	5	5
Plutonium inhalation cases	1140	1501
Chelating agent used	12	13
Deposition above 5% MPBB	98	101
Deposition above 50% MPBB	12	14

Note: MPBB = Maximum Permissible Body Burden.

Source: Modified from Parker 1973. Reprinted with permission of Springer-Verlag, New York, copyright 1973.

This can be compared with the summary from earlier days shown in table 19.3. Note that inhalation cases greatly exceed injury cases (i.e., wounds) in the experience at Hanford. Also, the relatively few cases treated with a chelating agent can be taken as a measure of the portion considered potentially serious enough to warrant decorporation therapy.

Summaries of contamination incidents by radionuclides other than the actinides are not easy to come by. The furor over the toxicity of the actinides has eclipsed the fact that human cases include a considerable cadre of radionuclides. Many of them have already been discussed earlier in this book. An informative overview can be found in the NCRP report already cited. This includes a short statement regarding the relative incidence of cases for each of the radionuclides shown in the table of contents (see above). These include, incidentally, cases of overexposure caused by misadministration in medical use of some of the radionuclides, as well as the more conventional avenues.

(a) These numbers may seem high. However, anyone who has spent appreciable periods in the chemistry laboratory has more than likely been wounded more than once by glass tubing or other equipment. Add to this the need for awkward manipulations within dry boxes, the fact that the solutions being used were frequently very "hot," and it is not surprising that even a tiny pinprick becomes a contaminated wound. Sometimes the person is not even aware of having sustained a pinprick wound.

Despite the preponderance of cases where entrance has been by wounds, the greatest concern has focused on inhalation and, to a lesser extent, on ingestion cases.

We will now review some of the major instances that attracted attention or led to clear advances in knowledge.

2. Specifics

This section makes no attempt at complete coverage for the reasons given above.

a. Zirconium

The urgency to have some means of therapy at hand led the Hanford group and those responsible for medical care at the U.K. installation at Windscale to prepare stocks of zirconium citrate solutions for possible clinical use. This was based entirely upon the animal work sparked by Schubert and the lack of toxic effects seen therein.

It was natural for Hanford to be the first in the U.S. since they had the greatest potential for exposure to radionuclides. W. D. ("Dag") Norwood reported on their early cases in 1955. There were three trials of zirconium in man (Norwood 1956).

The first was a small dose administered to an incurable patient to test toxicity; none was noted. The second and third were employees with small fractions of the allowable body burden of plutonium attained by inhalation and ingestion in the first case, by a small break in the skin in the second. Both received repeated doses of 600 mg of zirconium in citrate intravenously. The preparation was made according to the formula developed by Schubert and contained both zirconium and sodium citrate. The results indicated some effect, but only from the very early doses. Indeed, it appeared that little could be gained by a series of zirconium injections, an idea reiterated by Schubert.

Norwood could detect no untoward effects of the zirconium. However, he was concerned about the effects of the accompanying sodium citrate and concluded: "These studies would indicate that the sodium citrate is the limiting factor and not the zirconium in the intravenous administration of zirconium citrate." (Norwood 1956, p. 37)

At the Windscale Works of the United Kingdom Atomic Energy Authority, two cases of plutonium contamination were treated with zirconium (Graham 1956). The first involved ingested plutonium, the second a pinprick wound. Perhaps because of the well-understood problems of administering the needed quantities of citrate, the U.K. investigators used zirconium malate. In the first case, two courses were given, about 350 mg over twenty-six days and about 400 mg spread over eight weeks beginning six weeks after the first course. The effects on excretion of plutonium were not clearly discernible, due partly to the large variability in urinalysis results. In the second case, zirconium malate was given in a series of five 50-mg injections. Effects on excretion were not commented upon.

In these cases, a totally unexpected side-effect of the treatment became apparent, viz., vertigo associated with vestibulitis. As usual, no connection was made between the treatments and the patient's symptoms for a considerable period.

Let Dr. Graham tell the story as taken from his extemporaneous remarks at the symposium.

Regarding Case 1:

At the beginning this patient seemed quite well. He complained of an unpleasant metallic taste during and for an hour or two after each injection. On some occasions he felt a little nauseated and had to rest for a few minutes after the injection.

After the 5th injection, however, he had an attack of vomiting and he went off work for a few days. His own doctor treated him for a mild febrile illness with gastric upset. He was taken suddenly ill again 17 days later and this time was hospitalized in the Medical Department. He complained of nausea, headache, giddiness and general weakness. He looked pale and collapsed at first but soon responded to bed rest, excess fluids and glucose, sedation and an alkaline mixture. While under treatment he had a moderate intermittent fever.

At this time no one connected his illness with zirconium. It was known that he had suffered from "bilious attacks" in the past, also he had been invalided from the R.A.F. on account of nervous dyspepsia. When he had recovered from his sickness he went away on leave for a few days but during this time he vomited copiously on four occasions. Despite this it was decided to give further zirconium in the belief that mobilization of plutonium was more important in the long run than these attacks of "gastritis" and "biliousness."

As time went on his symptoms became distinctly more definable as true vertigo. It was by coincidence that a second case (described below) had meantime found his way to an aural surgeon who diagnosed labyrinthitis. It then became clear that the first case also had labyrinthitis.

Vestibulograms taken by the aural surgeon showed almost complete suppression of labyrinthine function on both sides and confirmed the striking similarity between case (1) and (2).

(Graham 1956)

Regarding Case 2:

This patient also complained of a metallic taste which led to a distaste for food on many occasions, culminating in an actual loss of taste which was sufficient to cause some distress. There were headaches too, often severe, but here again one was misled because he suffered also from sinusitis and a deflected nasal septum.

A sharp attack of vertigo occurred two days after the 5th injection and from then on vertiginous bouts were frequent and distressing. Vomiting was not a feature although he was often nauseated and lost his appetite.

In due course he went to hospital for resection of his nasal septum and the attention of the aural surgeon was drawn to the vertigo. It was then that a diagnosis of toxic labyrinthitis was made, thus providing an important clue to the truth about Case 1, as has been described.

The labyrinthitis was bilateral and loss of function became virtually complete. Avomine was given to control the vertigo. As time went on the tendency to vertigo attacks disappeared and a year later all seemed normal. The taste sense also returned within a few weeks. The headaches however had persisted and were migrainous in character. It was difficult to say whether now, three years afterwards, there is much connection between the zirconium and the headaches.

(Graham 1956)

Following this there was much scrambling to find an explanation. Some proposed it was because the zirconium malate solution had been autoclaved and some degradation products had been formed; others that it was coincidence. Mice were given very large doses of zirconium malate, some batches of it thought to have been sterilized,^(a) without any signs of abnormal labyrinth

(a) Dr. Graham was not fully certain of this point, and this author has not found any further work or discussion of the subject.

function. To a degree, it has remained unresolved, but the conservative conclusion was that man reacts differently from most of the test animals to these moderately large doses of zirconium salts, at least the malate.

These toxic effects essentially ended the clinical trials of zirconium, although it was sometimes added to EDTA-type chelators (Dobson 1956).

b. Early Trials in Man with EDTA-DTPA

Again some of the earliest work was at Hanford. "Dag" Norwood and the medical department put EDTA at the ready for possible clinical use, even while the laboratory work was incomplete. They proposed very small doses and ultraconservative approaches, but nevertheless felt that the need to prevent bone deposition of elements like plutonium warranted some degree of aggressiveness.

The first case described by Norwood (1956) was one from Los Alamos, handled jointly by Norwood and Harry Foreman. This was a deposition of seven-years standing, presumably from inhalation of spray or vapor. The EDTA was given by slow intravenous drip, a method applied regularly in the early cases because too rapid administration of the chelator seemed to produce kidney damage in animals (see section VI). A total dose of about 5 g increased urinary plutonium excretion about tenfold.

More details were given in a paper by Norwood et al. at the Atoms for Peace Conference (1959). The first accident at the Hanford Atomic Products Operation that led to a body burden above limits (during more than thirteen years of operation) was an inhalation exposure due to a defect in a copper supply line. Treatment was instituted on the third day after exposure. It lasted seven months and involved 142 1-g doses of Ca-EDTA.^(a) Of these, 71 days involved intravenous doses and 21 days oral doses. There was complete collection of all urine passed.

Total plutonium excretion in urine was about 0.037 μCi from a body burden estimated at 0.36 μCi initially. Of the total excreted in urine, 0.033 μCi was passed during the Ca-EDTA treatments. About 0.35 μCi appeared in the feces. It cannot be said that these results indicated accelerated removal from lung, but it can be postulated that some plutonium leaving lung was shunted into excretion in lieu of deposition in bone.

By the time of the Hanford symposium on the biology of the transuranic elements in 1962, Norwood (1962b) could report on treatment of five Hanford employees who had carried variable amounts of plutonium for variable periods of time. The principal finding was that DTPA (they had turned to it instead of EDTA because of greater effectiveness) was fully as effective for decorporation therapy in humans as in animals. Oral DTPA^(b) was only about one-tenth as effective as that intravenously administered in increasing urinary output of plutonium, but it was about equal in hastening fecal output.

An early joint report from Los Alamos and Hanford (Foreman, Fuqua, and Norwood 1954) gave an opportunity to describe some early Los Alamos cases treated with chelators. The first was a wound caused by breaking of a flask containing $\text{Pu}(\text{NO}_3)_4$ solution. There was surgical removal of some of the contamination and early administration of Ca-EDTA. The results are shown in

(a) One gram was a convenient dose size since this was what the commercial ampules contained.

(b) The cumbersome method of slow intravenous drip was still in operation for the intravenous doses, and patient resistance led to many trials with the oral route.

figure 19.13, taken from Foreman's discussion of the cases at the Argonne symposium in 1955 (Foreman 1956).

FIGURE 19.13. Urine excretion assay for Pu from wound case showing effect of Ca-EDTA. (Redrawn from Foreman 1956.)

Case 2 was an inhalation exposure. The increases in urinary excretion, while measurable after Ca-EDTA, were not nearly as spectacular, partly because treatment was delayed, and partly, it was thought, because exposure was by inhalation.

Another case involved ^{241}Am , ^{242}Am , ^{242}Cm in a "hot" mixture that exploded just before the ampule was to be opened, spraying the operator (an Air Force major) with the contents. After measures to remove as much activity as possible from the skin using EDTA washes, intravenous EDTA was started. Urinary excretion was rapid during periods of therapy, much slower during "rest periods." The latter were brought on by the patient's balking at the long-continued intravenous administrations. It may have been serendipitous, for the investigators were surprised to find unexpectedly large increments in excretion on resumption of therapy, a phenomenon that repeated itself several times.

Another early American case occurred at Berkeley and was described by Dobson (1956). A graduate student working with ^{241}Am at a level of 10^{10} dpm in

a glove box struck his left hand against sharp broken glass and "suffered a small puncture wound between the thumb and forefinger." Since preliminary evaluation failed to rule out a potentially serious medical problem, intravenous Ca-EDTA therapy was instituted. This began only one and one-half hours after the wounds were received. Urinary excretion was about a factor of ten higher during the periods with EDTA. Meanwhile, much was done toward wound decontamination and removal of seriously contaminated tissues by surgery. After seventeen days, treatment was interrupted because of evidence of incipient kidney damage, and the urinary excretion fell by a factor of about ten. A short period on zirconium citrate produced no observable change in ^{241}Am excretion.

Since the whole-body counter had just been put into operation at Argonne, it was considered appropriate to check the patient's body burden of americium using its 60-kV gamma rays. Marinelli made the measurements and calculated a body burden that agreed quite well with that calculated from the urinary excretion and amounts removed surgically. Dobson calculated that the EDTA therapy had reduced body retention by five- to tenfold.

French experience in the earlier days is described by Lafuma (1963). This concerns a wound contaminated with ^{239}Pu . DTPA was found to be extremely effective.

So much for early experience with plutonium and other actinides. There was much less with other radionuclides. The Hanford group had some experience with ruthenium, but not much can be said about clinical decorporation. Also, isolated remarks on other nuclides appear in discussion sessions at the several symposia cited and in annual reports, but we will have to bypass these. There are, however, some experiences in man with alkaline earths and other radionuclides that are of interest.

Of particular interest to the decade of the 1950s is the work done with the Marshallese exposed to fallout from a weapons test. (Details are in chapter 12.) Stanton H. Cohn describes the early attempts to alter the rate of removal of mixed fission products in this small population in a classic paper given at the IAEA scientific meeting in 1962 already cited (Cohn 1963). Additions were made in a personal interview with the author in September 1982 (Cohn 1982).

Cohn was at NRDL at the time of the work, although the published report came from Brookhaven, and the interview was there. As part of a mysterious and urgent message he received to prepare for a journey to the South Pacific were instructions to bring along all necessary materials for decorporation therapy. No hint was given as to what was to be decorporated! The fact that this request was made indicates again the urgency felt by all responsible for medical care of contamination incidents to "do something."

Cohn's report gives details of the exposure (chapter 12), including supplementary information obtained from pigs that happened to live on Rongelap. It concentrates on attempts to estimate the body burden of the exposed population by measurements of urinary excretion and other means. At fifty-two days after the event, an attempt was made to increase urinary excretion of the deposited fission products in seven Marshallese subjects^(a) using daily administrations

(a) One may wonder in view of the urgent request to take along materials for decorporation why the attempt was delayed fifty-two days. The most likely explanation is the time required to establish body burdens and to make decisions on who should be treated. Also, the magnitude of the contaminations were not as large as first expected.

of Ca-EDTA. The dose, administered orally, was 1 g per each twenty-five pounds of body weight. Urine was collected daily for five days. Mean gross beta activity, the only measurement possible under these field conditions, was about two and one-half times the pretreatment level. It was speculated, based on the animal experiments, that this represented largely rare-earth elements. No information was obtainable on possible amounts in individual tissues until the later work with whole-body and other external counting techniques (chapter 12). No reason is given for the relatively short period of therapy.

Japanese investigators reported simultaneously on the clinical status and treatment of the twenty-three fishermen exposed to the same fallout on the ship *Fukuryu Maru No. 5*. (Kumatori and Miyoshi 1963). Only two received decorporation therapy, viz., Ca-EDTA by intravenous injections over intervals of "about three months and seven months after the detonation." No increase of radioactivity in urine occurred.

Before we leave these early experiences, we should look briefly at a thorium incident that occurred at Argonne in the early 1950s (Hathaway et al. 1956). It involved ^{227}Th , which has a half-life of 18.2 days. A tiny puncture wound occurred through the glove in a glove box with contamination at 60,000 to 80,000 dpm. More to be on the safe side than because of conviction that dangerous amounts of activity were present, Ca-EDTA was administered. In contrast to expectations from animal experiments on thorium compounds, the EDTA was reported to have caused increased excretion. However, the rises are not nearly so large as with many other radionuclides. Marinelli commented that the form of the thorium (chloride) may have contributed to its mobility and that the ^{223}Ra daughter was preferentially removed from the wound.

These early clinical trials with chelators of the EDTA-DTPA type showed clearly that the basic predictions of the animal experiments could be applied to humans. They also failed to show significant untoward effects, with one exception, and that marginal. It must be emphasized, however, that the treatment periods were not really long by the standards of later work. Further, the work showed that split doses, even with significant rest periods between doses, did not unduly reduce effectiveness and could contribute greatly to the patient's acceptance of the therapy. In fact, doses after a rest period were surprisingly effective. Also, such pauses may have helped to prevent cumulative toxicity of the agents, as we will discuss in the next section. An exception to the above is the importance of rapid initiation of treatment to ensure that there be a good chance that chelation could prevent tissue deposition, particularly bone deposition. It will be noted that none of these studies included opportunities to study tissue retentions, except where whole-body counting was applied; and this was relatively rare in the early years.

3. Crescendo of Experience

The fifty-four cases summarized by Volf (1978), although they cover only plutonium, americium, and curium, give a reasonable overview of experience to 1976. His table is reproduced in modified form as table 19.17.(a).

Particular attention should be focused on the column giving the excretory multiplication factor. Factors from zero to as high as three hundred are evident.

(a) Since most of the references have already been cited in this book or will be discussed presently, only the name and installation are cited in this modified table.

TABLE 19.17. Decorporation of Plutonium, Americium, and Curium in Man. [Author, date, and location in bold.]

On balance, the therapy can be said to be worth considering for any case of significant potential for long-term effects. The reasons for the variability must lie partly in the very disparate dosage regimens, but some must reside in differences in chemical or physical form of the deposit or in factors not yet apparent.

A few of these cases are considered in some detail below to illustrate certain points. We will concentrate on work that extended over from significant to very long periods.

Probably the longest observation period concerns a twelve-year study in Pittsburgh of an individual exposed to ^{241}Am (Rosen et al. 1980). There had been earlier reports of both plutonium and americium from Pittsburgh (Wald et al. 1968) with interesting coincidence of body burdens measured by external counting and those derived from urinalysis, along with general recommendations for the management of contaminated cases. However, the one we choose to discuss represents the longest observation period in all of the reports. The case came to light through the discovery of alpha activity in urine specimens. In-vivo analysis in 1967 led to an estimate of a body burden of $1.8\ \mu\text{Ci}$ of ^{241}Am . Since the individual was working with americium oxide in powder form to prepare foils, the intake route was presumed to be inhalation. He was removed from the work in May 1967. In September 1967, weekly administrations of $(\text{CaNa}_3)\text{DTPA}$ were begun and were continued almost without interruption through 1974. Results were monitored by periodic measurements using in-vivo methods for the content of total body, skeleton, chest, and liver. Also, urine and feces were collected from September 1967 through December 1974, with spot samples subsequently, a monument to the dedication of both the workers and the patient. During therapy, average excretion rates in urine were increased by a factor of about ten. By the end of the reporting period, the body burden had been reduced to about $0.7\ \mu\text{Ci}$, considered to be mostly in the skeleton. No adverse effects from either the americium or the therapy could be found in liver or kidney function, cytogenetic status, or hematological status. The applicable permissible body burden at the time for ^{241}Am was $0.1\ \mu\text{Ci}$ with kidney as critical organ or $0.05\ \mu\text{Ci}$ with bone as critical organ. Therefore, this case, even with therapy, was well above limits even for occupational exposure and should be watched with care. Obviously, the reduction in body burden might have been much greater if the case had come to expert attention, and therapy had been instituted immediately.^(a) Nevertheless, there is no doubt that the therapy greatly reduced the liver content and removed in excess of one-half the body burden between 1967 and 1974.

A somewhat similar case of exposure to americium occurred in New York State. It has been followed by the workers at the New York University Institute of Environmental Medicine. The case involved a father and son exposure and thus provided an opportunity to compare both metabolism and therapy in the juvenile and the adult. The incident took place in the Albany, New York, area as the result of a home workshop project of the father and son. They were totally unaware of their contamination or that of their surroundings until it came to the attention of New York State Health Department authorities (Whalen and

(a) Therapy was begun very promptly after the situation was appraised, but an appreciable period elapsed before that, since time of exposure was estimated as having occurred in 1965 or early 1966.

Davies 1972).^(a) The contamination began in late 1963, and exposure may have continued until the problem was discovered in 1970. A fairly detailed report of the earlier findings was made at the IAEA symposium, Assessment of Radioactive Contamination in Man (Wrenn, Rosen, and Cohen 1972) and they continued in annual reports of the New York University Institute (Wrenn, Cohen, and Eisenbud 1977). The original source contained about 5 mCi of ^{241}Am .

In-vivo gamma-ray measurements were made of skull, lungs, and liver; radiochemical measurements were made of urine, feces, and blood. The only tissue samples obtained were deciduous teeth from the son saved by the family. Therapy with $\text{Na}_3(\text{Ca-DTPA})$ was initiated in 1970 and continued until 1976 in three separate installments, 1970, 1973, and 1975. In the 1977 progress report (Wrenn 1977), estimates were made that the ^{241}Am body burden of the adult had been reduced by 23% in six years, while the juvenile (ten years old in 1970) lost about 75% of the initial body burden. By 1976, the bulk of the body burden was in bone of both patients.

The NYU investigators took the opportunity afforded by this case to compare ^{241}Am metabolism in man to their ongoing work in baboons cited in section IV of this chapter. The conclusions (Cohen et al. 1976) are:

1. DTPA is much more effective in accelerating excretion of ^{241}Am in the juvenile, both man and baboon.
2. ^{241}Am removed from the skeleton by the DTPA treatment appears primarily in the urine of both species.
3. Excretion in feces is also enhanced in both species, but this was not primarily from skeletal tissues.
4. There was reasonable agreement between man and baboon on quantitative aspects.
5. The treatment depleted the tissue of zinc, again in both species, and resulted in inhibition of a zinc-activated enzyme.^(b)
6. The difference in mobility of ^{241}Am in the juvenile appeared even in the most recent chelation therapy period, when the juvenile was fifteen years old.

A general survey of research at New York University was given by Cohen (1981).

A further summary from this work was added to the published literature by Cohen, Lo Sasso, and Wrenn (1979). Estimation of the americium content of total body and three tissues and its change over a ninety-three-month period is shown in table 19.18 taken from this paper.

Note that the removal rate from skeleton was appreciable in the adult only in the first year, while some mobilization occurred in the adolescent at later times. Note also relatively larger amounts of americium in the liver of the adolescent as well as its continued mobilization.

One of the most dramatic incidents with americium occurred at Richland, Washington. An explosion at Hanford embedded contaminated debris and

(a) The father was an engineer with the New York State Health Department and was fully confident that the americium was firmly fixed in the source. It was through a routine check at the office that his clothing was found to be contaminated. Actually six members of the household were measured, but only the father and son had body burdens that prompted therapy.

(b) Later work indicated also depletion of manganese.

TABLE 19.18. Estimation and Sequential Measurements of ^{241}Am Distribution in an Adult Male and an Adolescent Male

(a) Decorporation therapy was administered during the periods between months 0 and 12, 37 and 38, and 57 and 58.

(b) No error terms have been assigned to these values, since it was determined that unknown positioning consistency, body size variability, detector refabrication, and changing biological distribution of ^{241}Am will all account for errors that may be larger than counting statistics alone.

(c) Values in parentheses are determined by extrapolation of skull measurement. Other values are determined as skeleton = total body + lung + liver; values so obtained for 12 and 17 months may be in error because of detector refabrication and calibration change.

(d) Not determined.

americium particles in the side of the head and face of a worker, Mr. McCluskey. The quantities were large. There is no question but the medical treatment, including chelation therapy, greatly extended the victim's life.

The first accounts appeared in a Pacific Northwest Laboratory report (Heid et al. 1979a), at which time the incident was two and one-half years old. This was repeated in an IAEA symposium paper published in the same year (Heid et al. 1979b). An idea of the extent of contamination and the importance of the chelation therapy is shown in figure 19.14.

FIGURE 19.14. Effectiveness of DTPA in reducing liver and bone burdens. (Redrawn from Heid et al. 1979a.)

A vivid description of the accident and of Mr. McCluskey's inspiring attitude and philosophy is contained in a lay press article in the *Reader's Digest* (Englehardt 1981) under the catchy title, "The Atomic Man." The article states that Mr. McCluskey was carrying over five hundred times the maximum allowable body burden of americium. While true, this is somewhat misleading, since much of the contamination represented americium buried in the skin and was thus somewhat superficial. However, part of the exposure was by inhalation also, so that the amounts are still enormous by any ordinary measure.

At a meeting of the Hanford Environmental Health Foundation Transuranium Registry in November 1982, the case was reviewed in depth, and the subject gave his personal version of the occurrences and his reaction to therapy.^(a) Pictures showing the extent of his injuries, which included damage to one eye, and his present appearance testified eloquently to the changes wrought. The data on the extent of contamination indicated that without treatment skin ulceration and the whole sad story of the early radiologists would have transpired as well as possible longer-term effects from the deposits in bone and liver.

A full scientific and clinical discussion of this case appears as a series of eleven papers prepared for a special issue of *Health Physics* (Thompson 1983). There are discussions of the facility, the medical management and chelation therapy, histologic and autoradiographic observations on skin, hematological changes, urinary excretion of trace metals, external decontamination procedures, radiation dose estimations, even the psychological aspects of the incident. It makes interesting and important reading.

Long-term follow up of therapy of *plutonium* contamination instances is documented in table 19.17. Nearly all show significant excretory multiplication factors. Dolphin (1976) makes special mention of a wound case described by Schofield et al. (1974) in the United Kingdom, where contamination was reduced first by surgical excision and then by extensive Ca-DTPA treatment. Because of breaks in the treatment periods, it was possible to establish quite clearly a phenomenon indicated by other work, viz., mobilization can occur at considerable periods after deposition, albeit with a reduced ratio between treated and untreated excretion rates.

In a summary table of sixteen United Kingdom cases, thirteen of them plutonium, one americium, one americium and curium, and one curium, the preponderance of evidence was that *clinical treatment could be successful for inhalation cases as well as for wounds*.

Worthy of special note is the use of the inhalation route for the administration of the chelator to humans. This began at Hanford (Smith 1979; see also case #17 in table 19.17, which was reported by Jech, Andersen, and Heid 1972). Small nebulizers were developed that greatly facilitated self-administration of the agent. A two-year study at the U.S. Savannah River plant (Jolly et al. 1972) made successful use of the nebulizer and shows a picture of it in use. It was also used at Savannah River for a curium inhalation incident (see case #39 in table 19.17), but without effect.

The Rocky Flats plant of the Dow Chemical Company fairly early reported on the results of up to two years of treatment after an acute intake of plutonium.

(a) He viewed everything that had been done as fully in his best interests and expressed gratitude for all that had been done.

Chelation accounted for removal of significant amounts (Piltingsrud 1964; Lagerquist et al. 1965; Lagerquist, Putzier, and Piltingsrud 1967). Indeed, one of the highest removal fractions in man was reported by Lagerquist, Allen, and Holman (1967) in treatment of a contaminated nitric acid burn at Rocky Flats. This was based on comparing the remaining body burden predicted from the Langham equation (chapter 16) and the amount excreted. It came to 96.5% removal! This is probably high but may represent unusual mobility of contamination from a burn area.

In earlier work, the Rocky Flats group compared the effectiveness of DTPA in a case of ingestion plus inhalation plus small acid burns to a simple small wound. Surprisingly, the effectiveness was much greater for the inhalation case. This illustrates a point brought out by others (e.g., Parker 1973) that the mobility of material from contaminated wounds can be quite variable and unpredictable.

The Rocky Flats people developed a useful "wound counter" for plutonium. Such instruments evidently developed independently elsewhere or found their way to other laboratories. Parker (1973) describes use of such an instrument, and it appears to have been in long use at Hanford.

Finally, we should mention the only case of pulmonary lavage recorded for the removal of plutonium in man. The work was done at the Lovelace Clinic in Albuquerque and the Inhalation Toxicology Research Institute on an individual with an estimated lung burden of 450 nCi of ^{239}Pu (McClellan et al. 1972a,b). It appeared in print only as an abstract but was discussed in some detail at the Seventeenth Annual Meeting of the Health Physics Society and at contemporary symposia. In addition to lavage, the subject received DTPA beginning on the eighth day postexposure. A total of 146 nCi of ^{239}Pu (plus a little ^{241}Am) were removed in eleven days of treatment: 59 nCi were recovered from the lavage fluid associated primarily with pulmonary macrophages, and 87 nCi appeared in excreta. The authors were satisfied that pulmonary lavage was a useful adjunct therapy. However, these results and others on man described above do not support the statement made from the animal work that lavage was the only effective way to remove radionuclides deposited in the lungs. Indeed, several of the cases of inhalation exposure quoted above from various laboratories indicate more mobilization of lung deposits in man by the chelators than would have been predicted from the animal experiments. Curiously, the investigators do not remark on this conceivably important difference.

4. Conclusions Regarding Clinical Experiences

This review of the efficacy of various therapeutic regimens for removal of deposited radionuclides in humans shows that by and large the research done first with animals was confirmed and extended in man. There were only a few instances of disagreement, and these tended toward greater rather than less efficacy in humans. Matters of toxicity and pharmacological comparisons will be reserved for the next section.

Despite the relatively low frequency of serious contamination incidents, a formidable body of knowledge has been put together. The NCRP report (NCRP 1980) gives a detailed discussion of treatment for internal contamination under the following broad headings:

Procedures to Reduce Gastrointestinal Absorption

Stomach-Lavage, Emetics, Purgatives, Ion Exchange Resins, Prussian Blue, Aluminum-containing Antacids, Alginates, Barium Sulfate, and Phytates

Blocking and Diluting Agents

Iodides, Strontium Compounds, Phosphate, Calcium, Zinc, Potassium, and Forced Fluids (for tritium)

Mobilizing Agents

Antithyroid Drugs, Ammonium Chloride, Diuretics, Expectorants and Inhalants, Parathyroid Extract, Corticosteroids

Chelating Agents [the longest section]

EDTA; DTPA [in various forms such as Ca-DTPA, Zn-DTPA]; Penicillamine; Deferoxamine

Lung Lavage^(a)

Finally, as an indication of the value attached to *prompt* therapy, in at least one country, it is reported that the French installations have "do-it-yourself" kits conveniently located near work stations. Each kit is for rapid self-therapy if a contaminating event is suspected. There are different kits for different types of exposure (inhalation, wound, etc.). This extent of preparation bespeaks considerable anticipated clinical usefulness for the procedures developed.

As might be expected, enthusiasm for these therapies (e.g., chelators) is not universal. Perhaps most outspoken was the group at Los Alamos, which has used chelators hardly at all for plutonium except for the early days when Harry Foreman was at the laboratory. Indeed, they questioned both the efficacy and safety of DTPA in 1968 (Schulte and Whipple 1968). Some of their reluctance seems to stem from one of the early cases described by Foreman, a female technician who showed large amounts of albumin in urine during the treatment period. Furthermore, she suffered ill health from then on, although no true causal connection could be shown between the treatment and subsequent ill health. They also cite other cases, which had barely detectable increases in excretion of plutonium, and felt that the early treatment interfered with evaluation of the true body burden and thus the seriousness of the incident. The paper by Schulte and Whipple established that the renal damage was not permanent and that the subsequent ill health was probably not related to the therapy. However, all seemed to agree to the need for conservatism in application until more research had been done. As we have seen, ample additional work has been completed, and chelation therapy has been applied to many other areas in addition to radionuclide depositions, but the fact remains that establishment of the presence of significant risk from the deposition is a *sine qua non* for instigation of therapy.

VI. Pharmacology and Toxicology of the Main-Line Chelators

The radioisotope toxicology establishment had to enter upon much research ordinarily associated with more conventional facets of pharmacology in order to work intelligently with the chelating agents. Likewise, much about the toxicology of the agents themselves had to be learned. The investigators had ample

(a) The approach in this section of the document is largely clinical, but it is clear much of the clinical work depended on the laboratory research. However, much of it came from general medical research and cannot be entirely credited to the groups and efforts we have reviewed in this chapter. For quick reference the reader is again referred to the table at the beginning of the NCRP report.

company among those interested in chelators—either as clinical tools in specific diseases, an area we must neglect entirely, or for treatment of heavy-metal poisoning.^(a) Nevertheless, some of the groups we have met in earlier sections found it advisable to pause for study of the agents themselves before undertaking further efforts at therapy. This was done as part of the internal emitter programs supported by the AEC and its successor agencies until the cutoff of funding initiated in the summer of 1979. The results have inherent interest and extend in significance beyond the problems of therapeutic removal of radionuclides.

There were efforts quite early to understand how the various agents behaved in the body (we are labeling these *pharmacology*) as well as any untoward or unexpected effects (we are labeling these *toxicology*). There was work with nearly all of the substances and procedures described earlier in this chapter. However, the area of greatest concentration involved the polyamino-polycarboxylic-acid-type compounds like EDTA, DTPA, etc., which we have discussed above under the rubric “Main-Line Chelators.”

A. Pharmacology (Pharmacokinetics, Pharmacodynamics)^(b)

The story starts at the same time and in the same places as the consideration of chelating efficiency for the removal of radionuclides. It was based upon strong and extensive experimental work done in the chemistry departments of industry and academe, which we have already alluded to, referenced, and discussed briefly. Some principles of the pharmacology of the agents emerged early (Foreman 1954, 1955, 1960; Schroeder 1960; Schubert 1954). A few of them are:

1. Stability constants measured in the test tube can frequently predict which elements are likely to be chelated and removed and which are not.
2. The positive predictions from the test tube do not necessarily follow exactly in vivo. The chelating agent must compete with “naturally occurring binding forces whether these be insoluble crystalline material in the skeleton, the forces by which the reticuloendothelial system binds materials (whatever they are) or the many naturally occurring complexing or chelating agents.” (Foreman 1954).
3. The agent must have a strong binding tendency for the metal to be removed, and the binding must be appreciably higher for it than the forces for naturally occurring essential metals to be of any real use.
4. The metal chelate must be readily excreted.
5. Stability constants measured under nonphysiological conditions are of little use.

It soon became apparent that EDTA was poorly absorbed from the gastrointestinal tract (Foreman 1960). This may be because EDTA has its iso-electric point at about pH 1.2. It may become quite insoluble at the pH of the stomach

(a) One of the broader overviews of both aspects of chelation and of its chemistry can be found in the excellent book by Albert, now in its sixth edition (Albert 1979).

(b) Some of the work borders closely on therapy, but we will consider it primarily pharmacological.

contents and be solubilized only slowly as it passes through the small and large intestines.^(a)

It appears that EDTA is not broken down (metabolized) in the body and is not conjugated like most drugs (Schroeder 1960) except for its combination with metals. For example, practically no $^{14}\text{CO}_2$ appeared in expired air after administration of EDTA labeled with ^{14}C . As a result, it is almost totally excreted, mostly in the urine if entrance is parenteral, mostly in feces if entrance is by mouth. This was found by Foreman and his group at Los Alamos using ^{14}C -labeled EDTA. Typical findings in the rat are shown in table 19.19, taken from Foreman (1953).

TABLE 19.19. Distribution of CaNa_2EDTA at Various Time Periods After Administration^(a)

Tissue or Sample	1½ hr After I.P. Injection	6 hr After I.P. Injection	6 hr After I.P. Injection ^(b)	24 hr After I.P. Injection	24 hr After Oral Adm.
Urine	85.22	95.73	96.66	94.56	10.30
Feces ^(c)	0.50	2.04	1.20	3.63	88.32

Liver	0.46	0.15	0.19	0.05	0.18
Skeleton ^(d)		0.30		0.12	0.08
Muscle ^(e)		0.13		0.28	0.36
Blood	1.65	0.07	0.04	0.01	0.04
Remains ^(f)	8.08	0.03	0.09	0.01	0.03

(a) Results are expressed in per cent of recovered dose per total organ or sample.

(b) 250 mg inert CaNa_2EDTA added to study effect of size of dose.

(c) Feces include contents of gastrointestinal tract at time of sacrifice.

(d) Calculations based on assumption that the skeleton equals 18 per cent of the body weight.

(e) Calculations based on assumption that the total muscle mass equals 40 per cent of the body weight.

(f) Includes heart, lungs, spleen, brain, gonads, adrenals and thymus, all of which were assayed separately but not reported individually, since none of these organs contained over 0.05 per cent, except in the 1½ hr period.

Source. From Foreman 1953b. Reprinted with permission of the Journal of the American Pharmaceutical Association, Washington, D.C., copyright 1953.

The behavior extended to other species including man (Foreman, Fuqua, and Norwood 1954) and to the other main-line chelators available (Foreman 1960).

(a) The people at Hanford (Baxter and Sullivan 1972) found that plutonium chelated with DTPA was absorbed from the intestine to a much greater extent (by a factor of about seven hundred) than unchelated plutonium. This may appear to be in conflict with the finding that EDTA (and DTPA) themselves are poorly absorbed. It is not in conflict because plutonium is so very insoluble that it does not take a very large absolute increase in numbers of molecules crossing the intestinal barrier to accomplish an amplification factor of the magnitude found. Also, the number of chelate molecules binding plutonium is still a small fraction of the oral dose.

Only a few compounds, those with lyophilic properties, discussed earlier, which were developed for special purposes, have significantly different distribution patterns.

Blood activity of $\text{Ca }^{14}\text{C EDTA}$ peaked at about 1% of the injected dose per cubic centimeter of blood immediately after intravenous administration. However, it fell rapidly to less than 0.001% at seven hours in the rat. Amounts after intramuscular or intraperitoneal administration peaked around 0.4% at about one hour and then fell rapidly also. After oral administration, the blood level never reached more than 0.04% (Foreman 1953).

As indicated earlier, penetration of EDTA into cells, even the red blood cell, was found to be minuscule. The substance came rapidly into equilibrium with a fluid volume slightly larger than the extracellular space, and then left rapidly as any very soluble substance does. Renal clearances were between 1 and 1.5 ml/min.

All of this led the investigators to the conclusion that multiple doses, or slow-drip infusions, would be needed to maintain an effective blood level of the chelator, and this was, of course, what was found in the experimental work described earlier. However, there were problems with this. There resulted a considerable volume of work on various dosage regimens and forms, extending over many years. Whereas the early work had been concentrated at Los Alamos and Hanford, the later efforts were more ubiquitously distributed in the United States, in Europe, and in the USSR.

Some of the work presented surprises. For example, even discounting relative toxicity, lower doses of chelator were sometimes more efficient at metal removal than higher doses. This led Foreman to speculate that "somewhere along the transport chain there is a membrane whose transfer potential for Ca-EDTA is saturated at low concentrations" (Foreman 1962, p. 356).

Catsch (1962) addressed the general principles of both the chemistry and pharmacology of several chelators in several dosage patterns. His primary conclusion using work done at Karlsruhe was that early application was of greater importance than the time pattern of dosage thereafter. However, as we already know, too much too soon can be toxic.

Despite the fact that the main body of the chelator molecule is not broken down by metabolism in the body, the binding to metal can be altered relatively easily, and free metal can be released *in vivo* (Foreman 1955).^(a)

In 1969, the Argonne group addressed the problem of effective dose regimen (Rosenthal et al. 1969). They tried DTPA doses spaced at three-day intervals and measured mobilization of plutonium in mice. The spaced doses were more effective, particularly for removing plutonium from liver. However, this does not address the prevention of deposition in bone by having a high blood level of chelator present early.

The Utah group became deeply involved with all aspects of chelation therapy beginning in the mid-1970s. We have already seen some of their results. In one of the annual reports issued soon after this work began, Stevens et al. (1974) considered alternate schemes for administering chelating agents based upon their solubility in lipids. Modifications of structure expected to aid penetration into cells reduced mobility of chelators but also reduced their effectiveness.

(a) This applies primarily to "foreign" metals. Normally occurring trace metals, with the possible exception of zinc, seem to be very firmly bound *in vivo* normally and can be removed only with difficulty.

Calder et al. (1978, 1979), also at Utah, tried a slow-release implant form of Zn-DTPA. They combined the Zn-DTPA in dried powder form with propylene-glycol 4000, beeswax, and peanut oil and implanted various types of pellets subcutaneously. The results were encouraging in terms of the basic problem of maintaining an effective blood level of chelator. But there were foreign body reactions at the implant site. Also, the implant required surgery, not a clearly advantageous trade-off with intravenous injection. They proposed to continue the work and develop better implants, but the funds were cut off and the work stopped.

In the same year, the Utah group (Lloyd et al. 1978) investigated the different frequencies of administration. They concluded that daily injections of Zn-DTPA are more effective for removing incorporated plutonium (in the beagle) than weekly injections of Ca-DTPA and were better tolerated because of the lower toxicity of Zn-DTPA.

In yet another study at Utah, Lloyd et al. (1979) researched the dependency of chelation efficiency upon time after the first injection. They tried to quantify the magnitude of the decrease in efficiency produced by delay in initiation of therapy with DTPA. The delays were from one minute to three days. The effect was more pronounced for removal of americium than for plutonium, but was significant for both. The retention in liver, kidney, spleen, and whole body is shown in table 19.20.

TABLE 19.20. Retention of Injected ^{241}Am or $^{237+239}\text{Pu}$ at 7 Days After Administration of 300 μmole of Ca-DTPA(a)

Dog	Age (months)	Injected Ca-DTPA ($\mu\text{mol/kg}$)	Delay to DTPA	Radionuclide Retention (%)			
				Total Body	Liver	Kidneys	Spleen

Looking in detail at bone (humeri), it appeared that early treatment had a disproportionately greater effect in reducing the content of ^{239}Pu in trabecular bone. Since this is the area where most bone tumors of the sarcoma type arise, the result is significant. The authors urge, on the basis of this and earlier work, that in a case of human exposure a large dose (1 to 2 g) of Ca-DTPA be given as soon as possible. This should be followed by a series of Zn-DTPA injections but with gradual lengthening of the interval.

The switch from calcium to zinc salt is based on the fact that the calcium salt is very effective when given initially in a large dose, while the zinc salt is better tolerated over a series of injections, even though it is not quite as effective.^(a) They urge continuing treatment, however, if there is much chance of translocation of deposits from lung or from a wound to the blood and hence to liver and/or bone.

The quest for a really effective regime for giving the EDTA-DTPA-type chelators orally has continued, especially in European laboratories (e.g., Taylor and Volf 1980). The complexity of the results and their application to therapeutics can be gleaned from the abstract of their paper, quoted below:

Abstract—The effect of orally administered chelating agents (DTPA, TTHA, TPHA, DFOA) on injected ^{239}Pu and ^{241}Am was studied in rats. Preliminary experiments with chelates given by stomach tube indicated that TTHA was the most promising agent for reducing retention of ^{239}Pu , but when the chelates were administered at lower concentrations in drinking water, DTPA proved equal or superior to TTHA in reducing the tissue content of ^{239}Pu and ^{241}Am : the calcium- and zinc-chelates of both DTPA and TTHA were equally effective. Prolonged, delayed addition of Zn-DTPA to drinking water (from day 4 to 25 post ^{239}Pu) at various concentrations revealed an exponential dose-effect relationship with respect to the total amount of Zn-DTPA offered, but irrespective of whether it was administered in 9 or 21 fractions. Up to one half and three quarters of the ^{239}Pu could be removed from the skeleton and liver, respectively. In order to achieve an equal effect on ^{239}Pu retention, about 30 times more Zn-DTPA had to be added to drinking water than the amount of Ca-DTPA injected. However, drinking Zn-DTPA [sic] in amounts only about 3 times as high as those of injected Ca-DTPA proved effective in reducing the tissue contents of ^{239}Pu . There was no evidence of toxicity in rats exposed to up to 30 mmoles Zn-DTPA in drinking water.

(Taylor and Volf 1980)

Also, the quest for derivatives with greater cell penetration described briefly in section VI has continued as a basic pharmacological problem on both sides of the Atlantic (e.g., Bulman and Griffin 1981, Harwell; Mays et al., 1981, Utah). Of particular interest is the calculation by Mays and coworkers of the minuscule amount of chelator that needs to penetrate cells to bind *all* of the plutonium present in a subject with a maximum permissible body burden of $0.04\ \mu\text{Ci}$ even if *all* of it is inside cells. With only 0.5% penetration of cells from a typical 1-g dose, the number of chelator molecules would exceed the number of plutonium atoms by a factor of four thousand!

(a) This was shown in beagles by Lloyd et al. (1977) at Utah and emphasized by Catsch on many occasions from review of Karlsruhe and Utah work. We will cite details in the next section.

Mays and colleagues point out that we really do not know in sufficient detail the amount of DTPA that enters cells of various types. They suggest careful tracer experiments to ascertain this fraction accurately, since it does not need to be large to be important. The Utah group also suggests that the process of pinocytosis (uptake into cells of very small droplets of fluid by an in-folding and pinching off of the cellular membrane) may play a part in cellular uptake of chelators, as of many other substances.

It will be noted in table 19.12 and earlier tables that the percentage of plutonium that is ultrafilterable is recorded beside many of the experiments. Throughout the work on chelation of the transuranics, especially plutonium, a distinction has been made between monomeric and polymeric forms of the radionuclides. This is on the theory that the monomeric form, i.e., ultrafilterable and thus either ionic or in very small aggregates of atoms, is handled differently from polymeric forms, which will have the properties of colloidal aggregates (chapter 4). The latter will be subjected to phagocytosis, trapped by the reticuloendothelial system, etc., while the monomeric form will not. Obviously, a really sophisticated system of therapy might aim in different directions if it were known that the material to be decorporated was predominately in one or the other form. Much very interesting animal research has been done around these postulates, but it has contributed more to our knowledge of the pharmacokinetics of radionuclides than to therapeutic regimens. For one thing, the distribution between monomeric and polymeric forms is subject to considerable change with time. Further, it is not easy to determine the relative proportions of deposited radionuclides in different forms in a case coming in for therapy. Thus, the approaches had to remain quite broad, indeed somewhat empirical.

We will complete this section with a quick review of some of the pharmacological aspects of removal of deposited metals from the lung.

With the development of ideas for administering chelators as aerosols, it became important to know the extent and rapidity of their absorption from the lung. It was determined fairly early at Hanford that there was substantial absorption of these entities on inhalation. A careful quantitative evaluation came from the Lovelace group several years later (Dudley, Muggenburg, and Cuddihy 1978). A solution of DTPA labeled with ^{111}In was administered to beagle dogs, and its absorption and translocation from various segments of the respiratory tract were measured. Percentage absorption after twelve to twenty-four hours were 16%, 48%, and 90% of the amount instilled directly into nasopharyngeal, tracheobronchial, and pulmonary regions, respectively. (Fiberoptic bronchoscopy was used for the deeper instillations.) Material inhaled into the upper respiratory tract as an aerosol was absorbed to a somewhat greater extent (23% versus 16% for the deep instillation). In both cases, there was longer retention in the blood stream after entry via the lungs than after intravenous injection, and appreciable amounts remained in lung. This work confirms earlier work done with rats in the United Kingdom (Stather et al. 1976).

The fraction absorbed from the upper respiratory tract, while not large, was considered significant and an important factor in favor of the inhalation/instillation route of administration, especially when coupled with the greater and longer blood retention times. Specifically, the chelator need not reach the deep lung to provide significant blood levels. Also, the presence of DTPA in lung as long as forty-eight hours after instillation was considered an important adjunct to possible reactions in lung with deposited radionuclides.

In this work, we see, as we have in other connections, that absorption from lung may be rather different from gastrointestinal tract absorption. In contrast to the very poor absorption of EDTA and DTPA from gut that we noted earlier in this section, the total absorption from lung was estimated at about 20%.^(a)

It is clear that basic research on the pharmacology of the chelators is far from finished.

B. Toxicology of the Main-Line Chelators

The fact that agents like EDTA and DTPA had inherent toxicity became apparent quite early in their use. Unfortunately, this occurred before the days of the stringent toxicity tests we are now accustomed to expect before any new drug can be used clinically. Therefore, some of the earliest signs of trouble turned up in clinical uses, albeit not ones for removal of radionuclides.

1. Kidney Damage

The first manifestations of unexpected toxicity were seen in patients receiving EDTA for reduction of calcium deposits in the body associated with metastatic cancer and in patients undergoing therapy for lead poisoning. Fairly severe damage appeared in kidney tubules in some patients receiving large doses of EDTA. There were two cases at MGH, both terminal patients, who came to autopsy (see Foreman, Fuqua, and Norwood 1954) and a case at Los Alamos (Foreman, Finnegan, and Lushbaugh 1956) of a worker who developed clinical signs of kidney dysfunction that reversed on cessation of DTPA treatment. Other earlier human cases are referenced by Foreman, Fuqua, and Norwood (1954) and discussed in detail by Seven (1960). There is even the possibility that the unexpected kidney damage contributed to the deaths of one or more of the terminal patients.

It became clear that the kidney lesion could be reproduced in rats (Foreman, Finnegan, and Lushbaugh 1956). It was a "toxic nephrosis consisting of severe hydropic degeneration of the proximal tubules." It could extend through other parts of the kidney structure even to the distal tubule with high doses or long-continued administration. However, it was surprisingly reversible after the injections were stopped. These lesions have been described repeatedly (Foreman 1960, 1962) and found to occur with DTPA as well as with EDTA.

There was considerable interest in the mechanisms of this effect. Some of the work was done within the internal emitter establishment, especially at Los Alamos, but much was also done in centers interested in therapy for heavy metals in general. It was tempting to relate the effects to removal of essential trace metals, possibly from enzyme systems. Alternatively, especially in the presence of complexes of mercury or other kidney poisons that might dissociate at the low pH of the kidney tubule (recall the role played by such processes in the toxicity of uranium described in chapter 2), a direct heavy-metal poisoning might play a role. At the symposium on metal binding in medicine held at Hahnemann Medical College, and already cited several times, Dr. Frederic Reiders

(a) In the same experiment, a dog receiving DTPA by gastric lavage absorbed about 8%, slightly more than that reported for rats or humans, but still well below the lung absorption.

from the Pennsylvania Department of Health suggested that zinc might be the essential trace metal mobilized by the chelator (see Schroeder 1960).

In the same discussion, Foreman described quantitation of the renal lesion in animals, by the so-called ED_{50} (effective dose in 50% of the animals). It was about 60 mg/kg, well above the minimal therapeutic level, but within the upper range of an active decorporation program. There did seem to be a threshold for the effects.

The doses required were sufficiently above the therapeutic level not to discourage use of the chelators except for contraindication of their use in the presence of nephritis. Also, in view of the reversibility of the lesions, it was suggested that the chelators be given in short courses with periods of rest interspersed.

In a later fuller discussion at a symposium held at Richland, Foreman and Nigrovic (1968) described additional work. Apparently the kidney lesion was much less likely to develop with Zn-DTPA. This was regarded as confirmation of the idea that zinc mobilization was important (e.g., removal from the zinc-dependent alkaline phosphatase enzyme). However, the toxicity of a manganese chelate (Mn-DTPA) was also lower than that of conventional sodium or calcium EDTA or DTPA.

2. Hypocalcemia

The possible upset of calcium homeostasis by these chelators has been alluded to many times already. Obviously, too rapid administration could produce tetany and convulsions. However, replenishment of calcium from body stores is sufficiently rapid that infusions at rates up to 15 mg/min of EDTA usually produce no marked changes in serum calcium level or symptoms of low blood calcium (Seven 1960). There is, however, marked variability in the response of different individuals.

Obviously, the addition of calcium to the solution helped considerably along with care in the infusion rate. Indeed, more rapid infusions are possible without hypocalcemia if the calcium chelators are administered (Seven 1960).

Symptoms like numbness and tingling in the fingers and around the mouth and face frequently follow these chelate infusions. These are like early symptoms of decreased serum calcium levels. However, they seem to persist even when the calcium chelate is given, a subject for further investigation.

3. Acute Lethality

These substances do not rate as chemical toxins of high potency. Yet, a few people have investigated their acute and subacute toxicity, and it was begun soon after the agents appeared on the scene. The first work was done by a group at the Department of Pharmacology of the Boston University School of Medicine (Bayer et al. 1952). They did both Ca-EDTA and Pb-EDTA. Acute lethality, i.e., a conventional LD_{50} , was difficult to obtain because the large amounts of material required frequently could not be brought into solution easily. Nevertheless, LD_{50} values were estimated. They were about 6 g/kg in mice, rats, and rabbits for intraperitoneal doses, less than 4 g/kg in rabbits after intravenous administration with no deaths at 2 g/kg. On repeated doses for 14 wk, these numbers were reduced to about 0.5 to 0.25 g/kg. Five doses per week were not toxic to rabbits over 105 days at levels of 20 to 40 mg/kg, but definitely toxic at daily doses of 70 to 100 mg/kg. The report is in abstract form and does not give details regarding the symptomatology or causes of death.

This Boston work does not seem to have attracted much attention among those engaged in the researches we have been discussing in this chapter. However, slightly later work at Utah, in the United Kingdom, and in West Germany did attract attention in the radionuclide chelation circles. Morgan and Smith in the United Kingdom (1974a,b) found considerable damage in liver, kidney, and duodenum and did acute lethality determinations. Extrapolation of their LD_{50} figures from mouse to humans predicted a value for acute toxicity of 660 g for Ca-DTPA. There was little effect of chronic doses equivalent to 10 g.

At Utah, Taylor and coworkers (1974) showed that injections of Ca-EDTA of 0.16 g at five-hour intervals caused death in beagles by four days. The lethality was attributed to removal of zinc. Much lower doses (up to 0.36 mmole/kg produced no symptoms except slight melena [blood in feces]).

At Karlsruhe, Planas-Bohne and Lohbreier (1976) used DTPA as both calcium and zinc salts and worked with rats. Forty-four weeks of treatment at 100 moles/kg twice weekly produced no adverse effects with either the zinc or the calcium salt. Continuous infusion brought about the typical toxic effects with the calcium salt but not with the zinc chelate. Repeated injections were not nearly as toxic as continuous infusion.

Of special interest is the finding that several dose fractions of Ca-DTPA were more toxic than single injections of the same amount. American and West German work contributed to this finding. Taylor and colleagues at the University of Utah gave 5.8 μ moles of $Na_3CaDTPA$ every five hours. The treatment was fatal within four days at a total dose of only about 8 μ moles/kg. Planas-Bohne and Ebel (1975) found also that several dose fractions of Ca-DTPA were more toxic than single injections of the same magnitude.

The reason (or reasons) for this phenomenon has not been proven. Obviously, the rapid excretion of EDTA- and DTPA-type chelators means that a single dose may leave quickly, thus allowing time for homeostatic recovery, while more sustained dosages deplete essential trace metals necessary for enzyme function.^(a) The Utah work takes up possible mechanisms in some detail.

These acute toxicity studies indicate a satisfactory but not a large therapeutic margin for the calcium and zinc salts, probably an insufficient margin for the sodium salt, that is, of course, not used anyway. Catsch (1976) remarks that the toxic doses of Ca-DTPA are fifty to one hundred times higher than the usual therapeutic dose. However, if the concentration in blood is maintained constant over a long time, the margin of safety narrows sharply, indeed to the point where continuous use of Ca-EDTA should be interdicted.

4. Relative Toxicity of Zn-DTPA

The idea of overtly substituting zinc for calcium in DTPA salts seems to have evolved largely in European laboratories. Among the principals was the group at Karlsruhe (Catsch, Seidel, Volf, et al.). If the toxicity of EDTA and DTPA involves zinc removal, as already discussed, the addition of zinc should counteract these effects and lower the toxicity. In a series of reports in the German literature, this premise was proved to be true for both lethality and toxic effects. Nevertheless, much attention had to be given also to the relative effectiveness. The best

(a) As we will see presently, inhibition of several enzyme systems, including DNA synthesis, has been recorded.

entrance into these developments for American workers is the summary paper by Seidel and Volf (1972) given at a Hanford symposium, Biological Implications of the Transuranium Elements. This work used rats and concluded that the two chelators were not very different in effectiveness (not in total agreement with later ideas) but that the zinc compound was distinctly less toxic (based on earlier work of Catsch [1964] and Catsch and Van Wedelstaedt [1965]).

Even the cumulative LD₅₀ for Zn-DTPA was about thirty times higher than that for Ca-DTPA, a severe test (Catsch 1976).

In the early 1970s, workers in the United Kingdom (Taylor and Jones 1972) also noted the lesser toxicity of Zn-DTPA and showed that there was transient inhibition of DNA synthesis in intestinal crypt cells by the calcium chelates but not by the zinc salt (see also Bohne 1972, quoted in Taylor et al. 1974).

In the United States, the Hanford group became interested quite early in Zn-DTPA. It was mentioned as a promising possibility by Norwood in the 1960s. However, most of their work was directed at relative effectiveness rather than at toxicity per se, except after inhalation.

The Utah group came down hard on the relative toxicities of calcium and zinc salts of DTPA as part of their extensive involvement with chelation research in the mid-to-late 1970s. There was an early paper in the annual report that showed low toxicity for the zinc salt; Lloyd and coworkers were so impressed by the lower toxicity of Zn-DTPA that they said, "We recommend that Zn-DTPA should replace Ca-DTPA as the treatment of choice, especially for protracted therapy in human cases" (Lloyd et al. 1977, pp. 93-94). Interestingly, this was at about the time that Catsch was backwatering some^(a) on Zn-DTPA because of findings showing lesser effectiveness, compared to the calcium salt. The Utah people used ²⁴¹Am in beagles as their test system and could find no real difference in effectiveness. The difference in toxicity was definite.

5. Effects on the Embryo and Fetus

These substances are teratogenic and considerably more toxic to the embryo and fetus than to the adult animal.

One of the earlier statements to this effect came from Norman Cohen at New York University in an annual report (Cohen and Guilmette 1974) and in a discussion session at the IAEA seminar, Diagnosis and Treatment of Incorporated Radionuclides (Cohen 1976).

The Utah group engaged deeply in the subject as part of their chelation research program. Fisher, Mays, and Taylor (1975)^(b) described toxicity of Ca-EDTA to the mouse fetus. At the high dose of 2.9 mmoles/kg there were no pups born. Only one fetus was found, and it was dead. A lower level of 0.36 mmole/kg had no apparent effect. This lowest level is still a factor of ten above the then-recommended daily dosage for humans, but the authors warn against incautious application of this apparent safety factor to human therapy because of the more rapid elimination rate of DTPA by rodents. Studies with Zn-DTPA were carried out in pregnant mice by Brummett and Mays (1977).

(a) Despite being regarded as the original promotor of the zinc salt.

(b) These authors quote somewhat earlier work on reproductive function and fetal development by Hurley and coauthors. This was contained in sources not available to the author.

Doses of the zinc chelate had no apparent effects on mouse fecundity or embryos or fetuses.

The zinc chelate was studied in more detail the next year—again using mice (Brummett and Mays 1977). This time, fetal toxicity was noted for Zn-DTPA, but it required a much higher dose. The lowest dose causing fetal damage in five days of treatment was 720 $\mu\text{moles/kg/day}$ for Ca-DTPA and 11,520 $\mu\text{moles/kg/day}$ for Zn-DTPA, a factor of sixteen larger. Also, while both agents caused abortions, fetal malformations (exencephaly) were found only with the calcium salt.

By the next year, the occurrence of fetal injury in two dogs was reported (Taylor and Mays 1978). The doses (30 $\mu\text{moles/kg}$) were injected each day starting at fifteen days after the first mating and continuing to birth of the pups. This dose had no detectable effect on the mother. Even the slight melena noted in nonpregnant animals did not occur. By contrast, the fetuses showed depressed birth weight (only one in five pups showed permanent stunting, however), changes in hair color to a silver-gray instead of the usual light brown (the normal pigmentation returned at three to four weeks of age), and there was definitely increased mortality of the pups in the first few weeks. Nearly all blood parameters were normal except for a variable degree of neutropenia (loss of white blood cells).^(a)

The Utah group became concerned that some of the toxic effects seen were resident in the method of preparation of their Zn-DTPA. They had been preparing the drug locally, and it contained 2 moles of sodium chloride for every mole of Zn-DTPA. On the other hand, material prepared for human therapy by the Sigma Chemical Company utilized a different process and was "a special batch of pure Zn-DTPA." A fairly extensive experiment was mounted in the mouse, not only to compare the two preparations but to investigate still higher levels of Zn-DTPA on the fetus (Calder et al. 1979). Acute effects were noted among dams at the highest Zn-DTPA dosage of laboratory-prepared agent. In fact, these animals died with severe kidney damage. There was some weight deficiency at birth in the pups at the highest level of either preparation, but no congenital malformations at all. The conclusion was that the "pure" preparation was even less toxic than the laboratory one, that the difference was not solely due to the sodium chloride, and that about four hundred times the prescribed dose for humans was needed to lower pup weights or cause kidney dysfunction in the mother. However, even longer-term experiments studying life span are needed and were planned, but abandoned by the cutoff of funds.

The Utah group, fairly early in their work on embryo and fetal toxicity, attempted an extrapolation of the finding on animals to the possible toxicity of Ca-DTPA to the human fetus (Mays, Taylor, and Fisher 1976). They concluded that Ca-DTPA did not have sufficient therapeutic margin to be used safely in pregnant humans. On the other hand, they felt that margin of safety for Zn-DTPA was adequate, though not large.

As we have seen throughout this book, Sikov and his colleagues at Richland have made a career of studying effects of radionuclides on the fetal and juvenile mammal. They worked with DTPA at about the same time as the Utah group (Sikov, Smith, and Mahlum 1975). As reported in an annual progress report, they

(a) This and the disorder of hair pigmentation seem to be related to what has been termed "the grey collie syndrome." It was postulated that this may have been due to chelation of copper.

found that one or two injections of 230 $\mu\text{moles/kg}$ Ca-DTPA had little effect, but 460 $\mu\text{moles/kg}$ were sufficient to kill the rat fetus. The injections were intraperitoneal given once a day on gestational days eight through twelve.

It is clear that these agents are more toxic to the embryo and fetus than to the adult and that chelation therapy of the pregnant human should be applied with caution and probably be limited to Zn-DTPA.

6. Pulmonary Toxicology

Reference to the extensive discussion of pulmonary toxicology in chapters 9 and 10 will recall that the effects of substances administered by inhalation may or may not duplicate those after absorption by other routes. In view of the considerable interest in administering the chelating agents as aerosols, a check on possible toxic effects of the DTPA-type agents on the lung was considered important. Quite naturally, much of the work was done at Pacific Northwest Laboratory. The primary investigators were V. H. Smith, J. E. Ballou, G. E. Dagle, H. A. Ragan, P. L. Hackett, and D. H. Willard.

In the 1973 annual report, it was shown that inhaled Ca-DTPA, at reasonable concentrations, produced no significant lesions in the lung except for a few emphysematous-type changes. A more complete picture was given at the IAEA seminar in 1975 (Smith et al. 1976) using rats, hamsters, and beagles. Taking the human dose equivalent as 1 g of Ca-Na₃DTPA glycinate/kg body weight, they gave from one to four human dose equivalents. The rats and hamsters developed what was referred to as a "transitory vesicular emphysema." It was not found later than three weeks after termination of the exposures.

In further Hanford studies, dogs received the agent in several doses (thirty minutes per day for five days) at an average of four times the normal human dose equivalent. There was enlargement of submucosal lymphoid follicles in the stomach and atypical cells in the alveolar lining. This was not present longer than four weeks postexposure. There is no mention of the transitory emphysema occurring in the dogs.

Since emphysema is not usually regarded as a reversible process, the PNL investigators did a repeat experiment using rats. Smith, Dagle, and Ragan (1978) gave inhalation doses equivalent to 0.4, 0.8, 1.4, and 2.2 times the dose usually administered intravenously to man. The aerosols had mass median aerodynamic diameters of 2.8 μm ($\sigma_g = 2.8$), and the maximum concentrations (2 mg Ca-DTPA/l) produced a dense fog in the aerosol chamber. Exposure periods ranged up to four hours. There was some loss of weight that was a function of dose. Blood changes were not significant. The histopathologic examination revealed no severe lesions, but there was some accumulation of histiocytes in the lung alveoli. There was also some fibrosis. A summary of the findings is given in table 19.21, taken from the 1977 annual report.

Although the lesions were in high incidence (note last column of the table), they were not severe even at the highest doses. The only incidence of concern was seen after twelve consecutive exposures. Single exposures were essentially innocuous. The incidence of emphysema was not different from that in the controls in this experiment.

The authors themselves do not draw conclusions from these data. It is apparent, however, from our review of other work that pulmonary pathology would be unlikely to take precedence over kidney, gastrointestinal tract, and other systems even on inhalation of the agents, but it cannot be disregarded.

TABLE 19.21. Incidence and Severity of Lesions in Lungs of Rats 21 and 42 Days Following Various Treatments

Lesion	Control Groups(c)			Incidence(b) in all Control Rats	Treatment Groups(c)					Incidence(b) in all DTPA Treated Rats

(a) Average grade of lesion = lesion grades/number of rats with lesion. Lesions were ranked 1 = very slight, 2 = slight, ..., 5 = very severe. No lesions were found deserving a grade designation >2 in this study. One rat in High Dose group died but was not examined.

(b) Fraction of rats among all control or among all treated rats with lesion.

(c) See Table [3.44] for dose and treatment information.

Source: Modified from Smith, Dagle, and Ragan 1978.

The other important facet of pulmonary toxicology arises from lung lavage with the chelators. The Lovelace and Los Alamos groups have addressed this problem. The work seems to have been confined to estimating the risk of the lavage procedure itself without chelator present. We must assume that the toxicity of the chelator when administered by the lung lavage procedure is not changed from other methods.

Muggenburg et al. (1976) did risk estimates using a series of ten lung lavages in ten beagles. No changes in cardiopulmonary function were observed with moderately elaborate testing methods. There was a transient and mild reaction heard on auscultation as "scattered, moist rales" and a slight elevation of body temperature. Histologic examinations at seventy-seven days revealed evidence of low-level pneumonitis and alveolar accumulations of macrophages and other cells. The areas of damage did not show evidence that they would become permanent. Broadly, the authors conclude that multiple lung lavages carry little biomedical risk. To be on the safe side, this experiment should be repeated with

chelator present in the lavage fluid since addition of it is contemplated for human therapy in some cases.^(a)

A somewhat more cautious estimate was made by George Voeltz (the Los Alamos physician we met in connection with the plutonium workers in chapter 16) at a symposium of the Health Physics Society held in Albuquerque, New Mexico, in January 1983. Voeltz estimated the general risk of lung lavage to the average human patient as 0.2% to 0.5% for one lavage, 0.4% to 1% for two lavages, and 2% to 5% for ten lavages. This is a summation of all types of risk. While not large, these risks speak for doing whatever is possible to increase the effectiveness per lavage (see Mays et al. 1981).^(b)

7. Toxicity of Puchel

In section IV, we learned of a chelating agent, not strictly of the EDTA-DTPA type, developed in the United Kingdom that showed considerable promise for removal of recalcitrant deposits of plutonium. It was, therefore, a disappointment to find that toxicity has turned up with it. In a report by H. Smith, Stather, and Stradling (1982) of the National Radiological Protection Board (NRPB), given at a meeting of the decorporation group of the committee on internal emitters of the European Late Effects Project Group (EULEP) held at Mol, Belgium, it seemed that mice had a high LD₅₀ at one day (900 μ moles/kg or 700 mg/kg) and that surviving animals showed normal behavior, food intake, and weight gain. However, after repeated intraperitoneal injections of sodium Puchel, liver damage appeared in a few months in hamsters.

These findings prompted the NRPB people to urge more extensive toxicity studies in several species before any further consideration is given to using Puchel in humans. We can be sure that this will be done if the U.K. funding continues.

8. Miscellaneous Toxicological Findings

In addition to the entities described above, there have been reports of other toxic effects. Some of these are more or less isolated findings. Others are of only slight significance. We will list them along with the originating investigator, but without extensive comment. Many are found only in the early comprehensive review by Seven (1960).

- a. Thrombophlebitis (Seven 1960)—Since these agents were sometimes hypertonic when given, some cases of vein irritation were noted. It was recommended that they be administered at strengths no greater than 0.5% in solution in 5% glucose in water or saline.
- b. Systemic reactions (Seven 1960)—Malaise, fatigue, weakness, excessive thirst, as well as numbness, tingling, yawning, nasal congestion, and prolonged

(a) Recently, another long-term follow-up, this time of lung lavage after inhalation of ¹⁴⁴Ce, came from Lovelace (Muggenburg, McClellan, and Boecker 1981), as well as a report on removal of inhaled plutonium and americium with lung lavage and DTPA (Muggenburg, Mewhinney, and Guilmette 1981).

(b) In the 1981 discussion, Mays came up with the idea of using ultrasonic vibration to help loosen deposits of insoluble materials in the lung so that they could be removed more readily by lavage and thus reduce the risk.

sneezing; sometimes temperature elevations, have occurred in man. Hypocalcemia may be behind some of these; interference with enzymatic function in others.

- c. Histamine-like reactions (Seven 1960)—These have mostly been minor.
- d. Glycosuria (Seven 1960)—Sometimes seen in patients with Wilson's disease being treated with the chelators.
- e. Anemia (Seven 1960)—Unusual.
- f. Dermatitis (Seven 1960)—From use of disodium EDTA for prolonged periods.
- g. Hypotension (Seven 1960)—Not serious but may indicate vasodepressor activity.
- h. Embolic Phenomena (Seven 1960)—Particularly seen in vigorous treatment of patients with calcium deposits in heart valves. Since the agents are sometimes used to mobilize calcium from deposits on blood vessels, a finite chance of embolism has to exist.
- i. Interference with DNA Synthesis (several authors)—The fact that DNA synthesis can be interfered with by these chelators has been demonstrated in animals. Usually it is around the idea that zinc depletion affects the enzymes involved (Weber 1969, West Germany).
- j. Brain damage in beagle fetuses (Mays et al. 1981)—This report concerns Ca-DTPA at a dose of 30 μ moles/kg. Over half of the live-born pups died during the first week with "gross and histological evidence of brain damage" (Mays et al. 1981, p. 352). This should be followed up, especially since the dose does not seem to be high.

9. Approval of Zn-DTPA by the Food and Drug Administration

It must be noted as something of a triumph for the care and completeness of the toxicological work on these main-line chelating agents that approval has been given in the United State for clinical use of Zn-DTPA as an investigational drug for decorporation therapy of actinides. Many individuals worked hard to foster this step, which was nursed through the approval process in part by C. C. Lushbaugh (1981) and colleagues (Lushbaugh and Washburn 1979) at the Oak Ridge Institute of Nuclear Studies. The IND number is 14,603. (Special approval was given for use in Mr. McCluskey at Hanford, as described earlier.)

VII. Summary and Commentary

In the chapter on radium and later in the chapter on fallout, allusion was made to ideas and procedures for removal of or prevention of deposition of radioactive materials, especially long-lived isotopes in the body. A considerable effort went into experiments with animals and trials in humans. In the beginning, these relied primarily upon manipulations of diet or of physiological processes. Near the end of the decade of the 1940s, partly as a result of work done on complexing agents during the war, the major line of attack shifted to these. It began with attempts to solubilize heavy metal cations by such relatively normal anions as citrate. The rapid metabolism of these resulted in disappointingly short complexing periods. Next came attempts at metal displacement by other elements such as zirconium. This was promising until unexpected toxicity of zirconium in humans intervened.

British anti-lewisite (BAL), developed during the war, effectively removed or prevented the deposition of several radionuclides. However, the nuclides of

most concern, i.e., the long-retained bone-seekers, did not respond to therapy with BAL. It did work well for a soft-tissue seeker, ^{210}Po . The major avenue of attack since the early trials has been complexing by agents related to the common detergents, the so-called chelating agents (see text).

The work described in this chapter would be very incomplete if we adhered to our general policy of emphasizing studies in the United States. Therefore, the chapter is quite broad and contains summary tables of work in many countries.

Since the process of chelation is not apt to be common knowledge, a portion of the chapter is devoted to the chemistry of chelators and chelation. Substances such as EDTA (ethylenediaminetetraacetic acid) and DTPA (diethylenetriaminepentaacetic acid) are potent complexing agents for metals normally in the body as well as added metals. Thus, doses need to be carefully controlled to prevent, for example, undue removal, sequestering, or excretion of body calcium. Partly on this basis, new agents were synthesized and tried for possible increase in removal of the elements of concern (e.g., plutonium and other actinides) relative to the complexing of normal body constituents.

The experimental work with animals was extensive and is summarized in considerable detail in the chapter. There was no doubt that the chelators would work. However, they were most effective if given very soon after intake of the offending metal. Significant delay reduced effectiveness markedly. Long-term deposits, especially in bone, frequently responded hardly at all to chelators.

In addition to the animal work, there were several laboratory trials with human volunteers. These showed quite satisfactory similarities to the findings in animal experiments.

The importance of removing deposited, or about-to-be-deposited long-retained radionuclides led to many therapeutic trials in humans. Even before much of the animal work had reached reliable volume and consistency, the emergency dispensaries of large nuclear centers had chelation procedures ready and used them in several cases. In addition to the removal of systemically deposited radioactivity, much effort went into the use of chelators in the treatment of contaminated wounds.

Some of the accidental exposures and their clinical management are reviewed in the chapter. There was no doubt that the therapy could increase excretion rates. The decrease in body or organ burden was considerably less dramatic than the temporary increase in excretion rates.

Special techniques were applied to inhalation exposures. It was considered important to attempt to remove deposited radioactivity before it could be transferred to bone or sequestered in fibrotic tissue in the lungs. Thus, pulmonary lavage with various substances, including chelators, was experimented with and given at least one clinical trial for plutonium removal.

As with nearly all therapeutic modalities of considerable potency, the chelators were not without potential untoward effects. In addition to immediate reactions such as hypocalcemia, noted above, there were longer-term effects. Among these were kidney damage, pulmonary effects, and effects on the embryo and fetus. As a result, the search still continues for new and different agents. Among these are ligands of tetracatechoyl, called LICAMs, synthesized and tested at Berkeley; agents aimed at removing that portion of the radionuclide that deposits in fat (lipophilic compounds) studied at Argonne National Laboratory; attempts to improve the intracellular penetration of chelators; adjunctive therapy, studied at Los Alamos, and so-named because the agent acts as an adjunct to the chelators; and others.

In many laboratories, investigators have either persisted with or returned to more physiological methods, including manipulation of hormone balances, blocking and diluting agents, and measures to reduce gastrointestinal absorption.

On balance, it can be said that much has been learned about the metabolism, the complexing ability, the changes with time, and other parameters of deposited radionuclides from this work on therapy. Some human lives have been saved or at least materially prolonged by the therapeutic measures taken. Toxicity can be ameliorated by dividing the dose. However, no solution has been found to the need to act quickly, i.e., to get the complexing process started before the radioelement can become "fixed." As a result, clinical judgment becomes of prime importance. Frequently, physicians must decide whether or not to institute chelation therapy before they have definite answers from biopsy or bioassay samples, whole-body counting, or other means to tell them the likely dose. Thus, physicians and radiation protection experts must collaborate closely in developing early estimates of the probable deposition. Fortunately, the number of cases even approaching levels where therapy might be advised is small.

Capsule Chronology

- 1913 Hevesy and Paneth use radium D (radiolead) as indicator in analytical chemistry.
- 1920s Blumgart and colleagues at Harvard use radium C (^{214}Bi) injections in humans for study of circulation. Also did a few tracer experiments in man with ^{226}Ra and ^{222}Rn . (These may have preceded the work with bismuth.)
- 1923 Hevesy and Paneth use radiolead as indicator in plant metabolism.
- 1926 Radon-222 "milked" from radium for preparation of radon seeds (Failla, Columbia; and others).
- 1932 Invention of cyclotron, the most used accelerator in medicine and tracer chemistry (see chapter 5).
- 1934 et seq. Tracer chemistry and predecessors of nuclear medicine. Work done around the major accelerator installations (Berkeley, Carnegie, Columbia, MIT,^(a) Rochester, Washington University, and others). Included much instrumentation development.
- 1934 First manmade radioisotopes (Curie and Joliot, France) using alpha particles from ^{210}Po (more in chapter 5).

Berkeley group confirms production of new elements by deuteron and proton bombardments in the new cyclotron (more in chapter 5).
- 1937 Use of radiosodium in man at Berkeley (Hamilton and Stone).
- 1938 Hertz, Roberts, and Evans apply radioiodine to patients. Also do animal studies (MIT-MGH).

Hevesy publishes manual of radioactivity.

Radioisotopes of iron revolutionize ideas of iron metabolism (Hahn, Bale, and Whipple, Rochester).
- 1939 "Medical cyclotron" at Crocker Laboratory, Berkeley, described by Lawrence.
- 1940 Astatine-141 begins to be studied at Berkeley as a possible substitute for radioiodine (Hamilton and Soley).
- 1942 Marinelli formulates basis for calculation of internal dose. It gradually grew in collaboration with Quimby and Hine to become the "classical" system (Memorial Hospital, New York; Columbia University).
- 1944 Radiocolloids proposed as a way to distribute beta-radiation dose to the reticuloendothelial system (Jones, Berkeley).
- 1945 Concept of rep formulated by Parker. Published in open literature later.
- 1946 Iodine-125 isolated.

Distribution of reactor-produced isotopes begun (AEC).
- 1947 First edition of Kamen's classic on isotopic tracers in biology published.

(a) For abbreviations and acronyms, see Appendix D.

- 1948 Hevesy's book on radioactive indicators published.
Marinelli, Quimby, and Hine discuss dosage determination with radioisotopes (Columbia University).
- 1948-1965 The era of therapeutic intent.
- 1949 Chemical principles elucidated for preparation and use of radiocolloids (Gofman, Berkeley).
Controlled selective localization of radiocolloids described in bone marrow, liver, and spleen (Dobson, Berkeley).
Bolus of sodium ^{24}Cl used to measure circulation time (Prinzmetal). Followed by other techniques in the 1950s.
- 1949 et seq. Gallium-72 suggested for bone cancer diagnosis and treatment (Dudley and many workers at Oak Ridge Institute of Nuclear Studies). Later replaced by ^{67}Ga and ^{68}Ga , but these were used in scanning.
- 1950s Cellular-level work begins with tritium and iodine-labeled nucleic acid precursors.
K. Z. Morgan chairs internal dose committees of NCRP and ICRP. Internal dose unit is developed at Oak Ridge.
Parker's proposal for dose units published.
Development of radioactive antibody approach to therapy begins (Bale and Spar, Rochester). Review in 1957.
Astatine work continues at Berkeley (Durbin and Hamilton).
- 1951 Mechanical radioisotope scanner automated by Cassen and coworkers (UCLA). Called a "scintiscanner."
Transmutation effects postulated for ^{32}P in bacteriophage.
- 1952-1955 Idea tried of using neutron capture therapy using radioisotopes as carriers, e.g., boron (Sweet, MGH; Farr, Brookhaven).
- 1953 Considerable further study of gallium for therapy (Brucer, Oak Ridge).
- 1954 Society of Nuclear Medicine (U.S.) organized.
- 1955 Atoms for Peace plan announced. Great increase in availability of radionuclides for all purposes (AEC).
"Gammicon" described (Mueller and Myers, Ohio State). Other instruments for same purpose developed rapidly.
- 1956 More from Hine and Brownell on dosimetry.
Colloidal gold preparations in general use.
- 1958 Scintillation camera described by Anger (Berkeley). A major advance in diagnostics.
- 1959 ICRP/NCRP major publications on limits for exposure of workers to radionuclides.
Publication of description of Anger camera at second Atoms for Peace Conference (held in 1958).
Effect of tritiated thymidine on mouse spermatogonia (Johnson and Cronkite, BNL). Also 1955, 1957, and 1958.

- 1960s** Antibody approach begins at Roswell Park (Pressman, Yagi, et al., Buffalo).
Modification and expansion of ICRP/NCRP dosimetry by Snyder et al.
Much on possible induction of leukemia by radiation therapy for thyroid disorders. Continued through the 1970s.
- 1960** Use of ^{125}I suggested for in vivo scanning of thyroid (Myers, Ohio State). Expanded in 1963 by Harper et al.
Plastic and ceramic microspheres introduced for medical use. Coated with a radionuclide of choice.
- 1961, 1963** Cell renewal processes in human rectal mucosa studied with labeled precursors (Cole and McKalen, Western Reserve University).
- 1962** Iodine-123 suggested for scans in preference to ^{131}I (Myers and Anger, Ohio State and Berkeley).
Tritium-labeled drugs considered for cancer treatment (Marrian et al.).
- 1963** Second edition of Quimby and Feitelberg's book on dosimetry.
Lipkin uses tritiated thymidine to measure generation times and proliferation cycle in cells of human intestinal tract (Cornell and Sloane, Kettering).
Use of $^{99\text{m}}\text{Tc}$ reported for scanning of several organs. Substitute for ^{131}I (Harper et al.). Use grew very rapidly because of large reduction in radiation dose to the patient.
- 1964** MIRD system for internal dosimetry is launched as substitute for "classical" (Marinelli et al.) system.
- 1965-1980s** The Era of Ever-Shorter-Half-Life Materials for use in diagnosis.
- 1965** First try at treatment of leukemia in animals using radiophosphorus (Shkurkin and Lawrence, Berkeley). This is in addition to earlier use for polycythemia vera.
Muller expounds on local use of colloidal gold.
Tritiated water, tritiated thymidine, and ^{60}Co gamma rays compared for ability to induce chromosomal aberrations (Dewey et al., M.D. Anderson Hospital).
High-specific-activity radiocolloids suggested for lung scanning (Wagner, Johns Hopkins).
Oak Ridge symposium on radioactive pharmaceuticals held. Many survey papers (Cloutier et al.).
- 1966** Colloidal properties of lanthanides considered at symposium (Kyker, Oak Ridge).
Iodine-121 and -126 suggested for nuclear medicine uses (Myers, Ohio State).
Bond and Feinendegen conclude that all somatic effects of incorporated tritium are due to radiation dose. No significant transmutation effect in mammalian systems.

- 1966 Radioisotope "cow" developed for "milking" short half-life isotopes from long-life progenitors (Richards, Brookhaven). Commercial production facility developed. Used particularly for obtaining ^{99m}Tc . (A ^{68}Ga positron cow was used in 1964 by Yano and Anger, but much less than the developments of 1966 et seq.)
- 1967 Effect of tritiated thymidine studied on mortality and tumor incidence in mice (Johnson and Cronkite, BNL).
- 1968 First three MIRD pamphlets issued.
Burki and Okada publish on cell killing with tritiated molecules at low temperatures (Berkeley).
- 1969 Krisch and Zelle review work on transmutation effect. Small effect seen in fruit fly.
Special limits proposed for intake of compounds of ^{14}C and tritium (Vennart, U.K.).
Two more MIRD pamphlets issued.
Auger effect of ^{125}I emphasized (Auxier, Krisch, and Zelle).
- 1970s Much work on cellular, subcellular, and carcinogenic effect of tritiated nucleic acid precursors.
Accelerators begin a comeback for production of short-lived isotopes in situ.
- 1970 MIRD pamphlet on decay schemes.
Loevinger's publications on dosimetry.
- 1971 MIRD pamphlets 7 and 8 distributed.
ICRP reports on protection of patients in radionuclide investigations.
Review of uses and availability of cyclotron-produced radionuclides for medicine (Laughlin et al., Memorial Hospital, New York).
Tritiated thymidine reported to produce cancer in mice (Mewissen and Rust, Chicago). Problems with the strain used, however.
- 1973 Feinendegen and Bond find transmutational effect of tritium only when it is incorporated in very specific positions in specific nucleic acid precursors.
Cloutier and Watson write on radiation doses from nuclear medicine procedures.
Potential uses in medicine of ^{241}Am and ^{252}Cf described by Seaborg (Berkeley).
- 1975 Evans traces history of joint Harvard-MIT-MGH collaboration in nuclear medicine.
- 1977 Idea of dose commitment promulgated by ICRP.
- 1978 Simplified version of MIRD system published by Cloutier et al. (Oak Ridge).
Reference Man phantoms prepared by Snyder and expanded by Cloutier.

- 1979 NCRP report on tritiated and other labeled organic compounds incorporated in genetic material.
 Carsten reports series of investigations on tritium in nucleic acid. Definite transmutation effect persists, but only in special situations and in nonmammalian systems (Brookhaven).
 DOE study group on nuclear medicine instrumentation development concludes that governmental support is still needed at the frontiers.
- 1980 MIRD pamphlet 9 distributed (10, 11, and 12 announced).
- 1980s Possible resurgence of therapeutic applications—a possible third era in nuclear medicine with both diagnostic and therapeutic uses active. Includes further use of microspheres, of monoclonal antibodies, epithermal neutrons in combination with ^{10}B , of false precursors, spontaneously fissionable radionuclides, and photoactivation of, e.g., stable iodine.
- 1981 Mathematical and conceptual reconciliation of Marinelli and MIRD internal dose formulations (Robertson, Mayo Clinic, DOE).

Chapter 20

Selected Aspects of Nuclear Medicine and Tracer Chemistry

Overview

As its title implies, this chapter is not a review of either tracer chemistry or of nuclear medicine. It is a review of the ways in which the ideas, people, and installations we have identified in the earlier chapters of this book impinged upon these two fields, and they on them. The role of toxicological considerations is given top billing, and it is shown that either overt toxicity or a desire to minimize patient dose has controlled much of the history of nuclear medicine. These did not play such a key role in tracer chemistry. It is the role of the techniques and ideas developed for radioisotope toxicology and vice versa that are pertinent to the tracer chemistry aspects.

The early enthusiasm for therapeutic uses of radioisotopes is traced, including the "Atoms for Peace Program," and the principal investigators and institutions of the earlier period are summarized. Because of the development of the Medical Internal Radiation Dose system of dosimetry for medical radionuclides, this chapter seemed an appropriate place for a short discussion of dosimetry of radioisotopes, frequently called simply "internal dose" or "internal dosimetry."

Many of the radioisotopes considered are either purposely or through normal processes bound into the precursors of nucleic acids and can have very localized effects within cells. A fairly extensive discussion of cellular-level effects is therefore included. While tritium is given the most attention, iodine, carbon, and others are treated also.

After the broad discussions of dosimetry and cellular-level effects, a series of sections look in more detail at areas of specific work and specific interest. For convenience, these are divided, somewhat arbitrarily, into eras. The first era is the one where therapeutic intent predominantly motivated the research (1948 to 1966). The second era (1966 to date), describes selected aspects of the tremendous growth of uses of radioisotopes for diagnosis, along with the relative decline of new ideas for therapy. The chapter ends with a quick review of some current ideas that could herald a recrudescence of therapy for cancer using radioisotopes and thus perhaps a third era yet to come.

More recent references have been added to this chapter than to many others, many of them in the proofreading stage of the manuscript. Since nuclear medicine is advancing very rapidly, this chapter must pay more attention to recent trends than have some of the other chapters. Nevertheless, it has to be inevitably somewhat out of date. Fortunately, this is history.

I. The Context

A. Purposes

The primary purpose of this chapter is to examine, in a general way, how the research and the investigators concerned with the toxicologic effects of radionuclides in the organism, particularly man, influenced, and in some instances made possible the development of the now enormous fields of nuclear medicine and tracer chemistry.^(a) It is also concerned with the contributions from these fields to the understanding of radionuclide effects and their uses in clinical medicine.

Concern for possible untoward effects of any drug used in diagnosis or therapy or of any agent handled in the laboratory for research purposes always goes hand-in-hand with the development and use of that agent. Thus, we have always had pharmacology and therapeutics accompanied by their obverse discipline, toxicology—sometimes in the thinking and activities of the same individual or group, sometimes in entirely separate groups or even institutions. Sometimes those on the cutting edge of developing new therapies or diagnostic procedures have viewed toxicology and the toxicologist as unwelcome deterrents to progress. However, it is now much more common to see conscientious application, realized or unrealized, by the physician and other professionals of the philosophy of gauging the risk as much as the benefit of any planned procedure.

The dichotomy of balancing desired results against undesired "side-effects" is especially well delineated in the history of the relationships of tracer chemistry, nuclear medicine, and radionuclide toxicology. This is partly because of the high level of concern over radiation effects, e.g., the radium cases (chapter 1), partly because the field developed after some of the gruesome mistakes in chemical pharmacology and therapeutics had come to light.

In the earlier days, the limitations of measuring devices and the lack of choice among available radionuclides made the amounts used even for tracer uses border on toxic levels. Even in applications of tracer chemistry where patients were not ordinarily involved, there was the constant concern that the radioactivity might interfere with the life processes to be studied. Only in the current generation of highly sensitive measuring devices and short half-life isotopes, and readily excreted radiopharmaceuticals has concern for toxic side effects almost disappeared.

This chapter will review historically these considerations and research of most pertinence to the practice of nuclear medicine and the use of radioisotopes as tracers. It will in no sense try to review the history of either nuclear medicine or

(a) This process was started in chapter 5. Let it be clear that we are dealing here primarily with uses of manmade radioisotopes and do not include as "nuclear medicine" the early uses of naturally radioactive materials as therapeutic nostrums.

tracer chemistry themselves. These have been described very adequately by others (e.g., Hamilton 1941 in chapter 5 and later sections of this chapter).

We will begin by tracing the origins and development of the three fields of interest and try to establish a bit of their genealogy.

B. Some Genealogy

In chapter 5, we reviewed the major steps taken in the decade of the 1930s to launch the fields we look at now. The reader is referred there for details of these early steps. To understand better the present situation, we need to trace, in a very broad way, the subsequent lines of development. I have chosen to do this in the form of a crude genealogical analogy.

In terms of the people doing the early work, there is no debate. The three fields (tracer chemistry, nuclear medicine, and radioisotope toxicology) involved the same people to a large extent. Indeed, they were not even separately named. They were one and the same. Hevesy quickly followed his idea of using a radionuclide (natural in origin) as a tracer in chemistry with administrations to plants and then animals. He considered potential effects as well as tracer applications. Robley Evans, among the first and clearly one of the leaders in radioisotope toxicology, put much energy and insight, along with his colleagues at Massachusetts Institute of Technology (MIT) and the Massachusetts General Hospital (MGH), into the development of iodine isotopes for biomedical use. Ernest Lawrence tried on himself some of his newly prepared ^{24}Na to show its rapid appearance in his finger tips. His physician brother John soon tried some of their cyclotron-produced ^{32}P for the treatment of leukemia in mice. Joe Hamilton was quick to apply the newly developed iodine isotopes to thyroid uptake studies and thought deeply of trying therapeutic applications as soon as enough material was available. (Note that this is the same Joe Hamilton who spearheaded the toxicologic efforts of the Manhattan Engineer District [MED] at Berkeley during World War II.)

The question of common ancestry for our three fields needs no further exposition. They are siblings. Should we, like all good genealogists, look for *the* patriarch? Let us try.

Gordon Brownell stated in his 1968 Nuclear Pioneer Lecture: "... the birth of nuclear medicine coincided with the invention of the cyclotron." In terms of having really usable amounts of isotopes available, this is obviously true, the pioneering work of Blumgart (chapter 5) notwithstanding. This would make Ernest Lawrence the father of nuclear medicine. Yet, he would have been the first to deny the honor and defer to others, including his brother John, who stimulated Ernest's interest in biomedical problems and did the first therapy experiment with a manmade radioisotope. Also, both would say it was Hevesy who fathered *the idea* in contradistinction to the machine and the application.

Hevesy was clearly the father of tracer chemistry. Somehow he seems more like a grandfather to nuclear medicine since he was further removed from it. However, he is consistently named as the father of both, and we should possibly accept Hevesy and Blumgart as joint founders of tracer chemistry and nuclear medicine.

Let us turn to the family interrelationships. Obviously, tracer chemistry and radioisotope toxicology are the older siblings. Which is the older is debatable. In terms of describing effects, the toxicology branch takes precedence. In terms of status as discernible disciplines, they seem to be almost twins. Like most

siblings, they did not lead identical or even very similar lives, even though they lived in the same household for many years. They used the same instrumentation and shared much methodology. Each attracted disciples. Because of the enormous usefulness of the tracer technique in all aspects of biomedical research, tracer chemistry became so popular that it had many more friends and playmates than radioisotope toxicology. However, there were few occasions where one sibling felt any need to horn in on the other's affairs. Instead, they helped each other.

Tracer chemistry had many sources of satisfaction as it developed to be the handmaiden to nearly all branches of natural science. The presence of scintillation detectors and the paraphernalia of tracer chemistry in the halls and laboratories of an institution gives one few clues as to what department one is in.

With the youngest sibling, nuclear medicine,^(a) the old homestead was only a comfortable incubator. Again, techniques, instrumentation, ideas, and people were shared initially. However, the field attracted a convergence of chemistry, electronics, nuclear physics, physiology, biochemistry, pharmacology, and medicine that quite outgrew the old habitat. Techniques, particularly the more recent techniques for use in diagnostic tests, have not only achieved remarkable sophistication (and bulk) but are in use in thousands of hospitals throughout the world. The old institutional research connection could not fully accommodate the youngest sibling.

In a sense, both tracer chemistry and nuclear medicine have been happy fields. Tracer chemistry has helped to unravel many of nature's secrets. Despite some disappointments (see later sections), nuclear medicine has placed undreamed-of resources in the hands of the physician and medicine in general. One of the field's pioneers and the historian of the Society for Nuclear Medicine, Dr. William G. Myers of Ohio State University, likes to refer to the scintillating images of distributions of radioisotopes used in diagnosis as "twinkling" atoms and imaging as "inside-out" radiology (Myers 1981a,b). Happy terms from "scintillating," happy people.

There have been occasions when the radiation toxicology (health physics) branch of the family felt the nuclear medicine branch was in need of both help—which came in the form of a flood of reactor-produced radionuclides—and some cautions about the chances some of their younger members seemed inclined to take with radiopharmaceuticals. However, it was no feud, and it resulted primarily in additional self-policing and a few not-too-welcome admonitions from the regulators.^(b)

The above should not imply that the radiation toxicology branch of the family never had any fun. Surely the thrust of this book shows that many people found it interesting, important, and worth supporting. But the enterprise has required, by and large, the hospitality of major institutions and the financial support of outside agencies, especially government, since its subjects could not be billed for services rendered. To follow our family analogy, the radioisotope toxicology branch has been more of a "stay-at-home." It has remained in surroundings more like the old homestead. Nevertheless, the family ties are still viable.

(a) The term "nuclear medicine" is ascribed to Robert Newell, the somewhat irascible but beloved radiological physicist who worked for many years at Stanford University.

(b) Remember that regulation, as it applies to the nuclear industry or to laboratory uses, does not apply to nuclear medicine, except for licensing and such things as waste disposal.

There are those who view the wartime emphasis on toxicology as an unfortunate diversion from the main tasks of developing medical uses. Now there are also those who feel little need to think of toxic side effects of the entities they are using. This is justified with current techniques, in part. However, it came about because of the constant search to do the job with ever smaller radiation doses. To do this required vigilance, humility, and close attention to possible toxic side effects.

Before going on, we should look back briefly at the phases in isotope sources. As already stated, there would have been no nuclear medicine and much less tracer chemistry but for the cyclotron, which inhabited the old homestead. While many of the radioisotopes produced were of such short half-life that all-night experiments were the rule,^(a) many of the radionuclides were too energetic and of too long half-life for optimal utilization. This led, in part, to the development of specific compounds that would carry the radionuclide to the desired area, preferentially, and then leave rapidly. Thus the field of radiopharmaceuticals was born.

At the end of World War II, a bonanza of radionuclides was made available from Oak Ridge and later from Brookhaven under the Atoms for Peace Program described in earlier chapters and later in this chapter. The idea then was therapeutic uses more than tracer applications. If the cyclotron helped to father nuclear medicine and tracer chemistry, the reactor should be dubbed their rich uncle.

This bonanza continues, but is now being modified by a return to cyclotron-produced isotopes with low-energy gamma rays and frequently no short-range radiotoxic beta-particle emissions. The object is further reduction of radiation doses (again under the influence of that sterner member of the family—radiation toxicology).

Modern technology has put small accelerators within the reach of many hospitals, both in the major centers and, it is anticipated soon, in community-type hospitals. With manufacture of radionuclides *onsite* possible, the problems of ordering, shipment, etc., can be reduced, and very short half-life materials can be used. This further reduces the collective radiation doses.

Despite these developments, it seems unlikely that the progeny of nuclear medicine will want or be able to forsake completely the old homestead with its assemblage of disciplines. Meanwhile, the lusty youngest sibling is contributing much in the way of instrumentation and methodology and in ideas to the other members.

C. Diagnosis Versus Therapy

The early applications of radionuclides in medicine were strongly weighted toward therapeutic uses. The analogy to Paul Ehrlich's "magic bullet" idea that developed around Salvarsan and the chemotherapy of syphilis influenced much of the early thinking and planning. This took two forms: (1) the utilization of radionuclides that were already known from the toxicologic work to localize strongly in certain organs, and (2) the preparation of compounds whose chemistry would dictate their specific localization in a tissue, particularly a tumor, and which could be labeled with sufficient amounts of a suitable radionuclide to deliver a therapeutically effective radiation dose to the tissue or organ.

(a) "From cyclotron to vein" was an apt aphorism (chapter 5).

The best early example of the first type was, of course, radioiodine. It was found, somewhat after the early tracer work, that large doses of iodine could be used in place of surgery for reduction or ablation of the thyroid gland in hyperthyroidism.

Another application was based on the idea that iodine would seek out and deposit in thyroid tumor tissue even when that tissue was in the form of metastases of a thyroid cancer sometimes far removed from the gland itself. This application was only moderately successful. There was considerable variability in the avidity with which metastases of thyroid cancers took up radioiodine. Sometimes large radiation doses could be given to the tumor tissue no matter where it had spread to. Sometimes the amount of uptake and resulting treatment success were disappointingly low. Much work was needed to establish optimal protocols.

Phosphorus-32 had been found through animal studies (again by those primarily interested in toxicology) to deposit largely in bone and bone marrow. The beta particles emitted were sufficiently energetic that the deposits in bone mineral irradiated marrow for a considerable period. It was on this basis that Lawrence and his colleagues (Shkurkin and Lawrence 1965) made that first try at the treatment of leukemia in animals. Therapy with radioactive phosphorus was reasonably successful in some blood disorders in humans—perhaps most outstandingly for polycythemia vera, a malady characterized by overproduction of red blood cells. Now such treatment has settled down to being more palliative than permanently curative (Shkurkin and Lawrence 1965) but is important nevertheless.

There are many other cases where a radionuclide has been chosen for therapy because of its tendency to localize in a given organ or tissue. We will examine some of these more specifically in subsequent sections. However, only a few have become permanent members of the therapeutic armamentarium. To realize maximum benefits, the doses frequently had to be quite large. Unwanted radiation of normal tissues was a constant problem—with all that means in side effects and general toxicity. Frequently, the target tissues became radioresistant^(a) or lost their avidity for the radionuclide in question.

In part, because of these problems, the carrier techniques were developed. The earliest of these and the one used most in early therapy involved radiocolloids. Using the knowledge gained in the general study of radionuclide metabolism and knowing the important role of the colloidal state in governing distribution and excretion, described in several earlier chapters, it was decided to exploit the normal functions of the reticuloendothelial system (RES) to bring about localization of radiation dose. The philosophy of internal radiocolloid therapy and specific examples are summarized well by Muller (1965). Colloidal radioactive gold is among the most successful of these, but radioactive chromic phosphate and several other preparations have had moderate popularity.

The principle here is, of course, to use the physicochemical properties of the colloid to determine tissue localization (e.g., uptake by components of the RES), then let the radioactivity “come along for the ride” rather than depending upon the chemical bonding of the radionuclide itself to the target tissue or cells. These have been especially successful for more or less superficial lesions to

(a) Development of radioresistance is, of course, a common problem in therapy using external radiation sources.

which the colloid could be applied. They have their problems for systemic use. It appears that only colloidal gold preparations possess almost no toxicity to complicate their use.

A different approach harks back to the radioactive microspheres we discussed in the chapters on pulmonary radiotoxicology. Suitable labeling of some of these microspheres is relatively easy because of their considerable stability. They have found many uses, which we will discuss presently, but most of them are still quite experimental.

Finally comes the more conventional radiopharmaceutical—a compound, nearly always organic, with affinity for a given tissue or organ and which can be labeled. These have not found much use in therapy because the thrust has been to develop compounds that will leave the body rapidly for diagnostic uses. Also, many of these compounds are readily destroyed by the intense radiation field needed for therapeutic applications.

Meanwhile, on the diagnostic side, things have been booming. Much of the work had its roots in radioisotope toxicology, but it soon began an independent existence. Three developments underlay these phenomena: (1) the growth of the radiopharmaceutical industry; (2) the production of short half-life radionuclides, many of which decayed by Auger electron production or other processes and had a minimum of beta radiation but sufficiently energetic x or gamma rays to make external counting easy; and (3) tremendous strides in measurement abilities. Two excellent summaries of the characteristics and the problems of radioactive pharmaceuticals are seen in chapters by Wagner and Emmons (1966) and by Charlton (1966), respectively, which led off an Oak Ridge symposium on radioactive pharmaceuticals.

As part of the chapter by Wagner and Emmons, a concept defined as the "Figure of Merit" is described. In its simplest form, this is the ratio of the dose to the target to that in the nontarget tissues. The higher this ratio, the better the pharmaceutical—as our toxicologic experience would have dictated. Also involved in design or selection of an ideal radiopharmaceutical are: maximum permissible radiation dose, time course of uptake and elimination from target and nontarget tissues, optimum time needed for measurements, and others.

Among the problems (Charlton 1966) are radionuclide purity, chemical form and stability, sterility (e.g., freedom from pyrogens), etc., as well as ease or difficulty of preparation and handling.

Yet another approach developed during the 1950s utilizes antibodies and the immune system and has been applied to both diagnosis and therapy. Nothing could be more specific than a specific antibody. If the target organ were cancerous and an organ- or tissue-specific antibody could be loaded with a significant dose of radioactivity and seek out the neoplastic tissue specifically, a potent therapeutic weapon might result. A considerable effort went into approaches comparable to, but more complex than this, especially in the hands of William F. Bale and his colleagues at the University of Rochester (see section IV 7 of this chapter; Bale and Spar 1957).

On the diagnostic side, analytic methods were developed called radio-immunoassays that could detect and measure minuscule concentrations of physiologic substances at levels unmeasurable by other techniques. This contrasts to most of the other diagnostic techniques of nuclear medicine that we have been enumerating by being an *in vitro* procedure. It was originated by Solomon Bersont and Nobel Prize winner Rosalyn Yalow (see *Seminars in*

Nuclear Medicine, Vol. 5, No. 2, 1975, for review and several references; also Myers and Wagner, 1975).

These developments have involved the private sector of our economy more than any of the areas we have examined so far in this book. The combination of suitable chemistry in the vehicle, suitable radionuclide properties, and ever more sensitive and automated measuring systems has resulted in the diagnostic uses becoming the major part of modern nuclear medicine and a booming industry for the instrument makers.

It must be said that on the whole the applications of radioisotopes for the treatment of disease have not fulfilled their initial promise.^(a) The field has narrowed to a few successful procedures. Unfortunately, it was the problems of toxicology and lack of specificity that underlay much of this retrenchment. The dose simply could not be localized sufficiently well or untoward sequelae averted dependably.

In contrast, the doses and toxic counterparts on the diagnostic side have been reduced drastically.

D. Who and Where

The early work in nuclear medicine and tracer chemistry in the United States emanated from the major centers we have been visiting throughout this book, particularly those of the early years, e.g., Harvard, MIT, MGH, and the University of California at Berkeley to start with. It went wherever cyclotrons were built. This soon added the University of Rochester, Washington University of St. Louis, and, later, Columbia University, and the Carnegie Institution in Washington.

The people, too, were the old familiar group. But this was not for long. Tracer chemistry was soon involved wherever modern physiology and biochemistry were being done. Medical applications did not spread so rapidly. They kept on steadily in the major centers throughout the years of World War II but did not spread throughout all of medicine until much later. Indeed, there was some question into the middle 1950s as to whether what we now call nuclear medicine should remain as a segment of radiology or a separate discipline in medicine. The prefix "radio" pushed it toward radiology as did the fact that most of the advances were being made by radiologists. However, internists, pediatricians, neurologists, even surgeons were coming to depend on the diagnostic services the new field could perform. As Myers and Wagner stated (1975), many felt that the surest way to encourage growth and be a resource for all of medicine was to recognize the activities as an entity. The Society of Nuclear Medicine was formed in 1954. The rest is history.

The number of diagnostic tests using the techniques of nuclear medicine is now several million per annum in the United States alone and would be still more if we include radioimmunoassay procedures. Yet, the lusty sibling really never fully forsook the old haunts. The American Board of Nuclear Medicine is a "conjoint entity" sponsored by three boards: Radiology, Internal Medicine, and Pathology (Myers and Wagner 1975). Three types of certification are possible—one in the whole field, one in nuclear imaging (administered by the American Board of Radiology), and one in radioisotope pathology

(a) It was originally considered enormous.

(administered by the American Board of Pathology). Our present and past radioisotope toxicology is most closely related to, although not identical with, the last named, of course.

In most institutions, one will find the nuclear medicine enterprise physically located hard by diagnostic radiology. Radiation therapy and therapy with radioisotopes are not always close by. The separation of diagnostic and therapeutic functions is becoming ever more general.

The balance of this chapter will engage us with some detailed examples of the generalizations made in this section.

II. Dosimetry

We have had relatively little to say so far in this book about the calculation of radiation dose from internally deposited radionuclides, except for some applications to maximum permissible intakes and standard setting in chapter 16. It is time now to review the subject briefly.

Obviously, nearly every experiment we have discussed has required or would have benefited from some sort of estimate of dose. In only a few instances, e.g., the work of Miriam Finkel, at Argonne National Laboratory (ANL), has the dose been rigidly couched in terms of the administered amount of material in the standard style of chemical toxicology or, as a permissible body burden in microcuries as Evans developed for radium (chapters 1 and 16). The hundreds of experiments we have reviewed gave us raw data in activity units per unit mass. The majority ended up, however, with translation of these to an absorbed dose in rad or rem,^(a) although sometimes in fractions of the maximum permissible dose (chapter 12). This has occurred in our field of interest because doses of external radiation were already expressed in physical units related to energy flux or absorption. The radioisotope people could not bear to have their results remain for long in units that could not be compared to external radiation. Indeed, frequently the same people did both kinds of work, and it was natural to want the same terms. The result was a system of calculations commonly called "internal dosimetry," "internal emitter dosimetry," or simply "internal dose."

The purposes are laudable, and the results have, on the whole, been very useful. A rather extensive research effort has been built up around them and should be reviewed.^(b,c)

In addition to putting research results with deposited radioisotopes in a form that allowed comparison with the huge literature using external radiation sources, another important reason was the needs of medicine. Even the earliest applications of radioisotopes in diagnosis and therapy inevitably required some system for estimating the associated radiation dose. The early development of the core system for internal dosimetry sprang in large part from the radiological physicists associated with biomedical installations, particularly medical centers.

(a) See Appendix D.

(b) We have waited for this chapter on nuclear medicine to compare the systems developed, even though they have broad application to much of this book, because of the development of the "MIRD" (Medical Internal Radiation Dose) system to be described.

(c) We should note how much further this system goes than does conventional toxicology, where frequently all that is given is the amount of material administered; not even, until very recently, the amount accumulating in a given organ or tissue.

It is not possible in this book to describe details of the schema of internal dosimetry; they are well summarized and easily available elsewhere. We will, instead, look at the basic nature of the schema and some of the problems associated with their use.^(a)

A. The Classical System

All of the formulations of the 1940s and 1950s, and into the early 1960s, utilized a system based on early formulations of Marinelli at Memorial Hospital in New York (Marinelli 1942) and subsequent work by Marinelli with Edith Quimby at Columbia University and C. J. Hine at Memorial Hospital (Marinelli, Quimby, and Hine 1948). A chapter on radioisotope dosimetry (classical type) was prominent in the first texts on nuclear medicine—a good example being the one by Moses Greenfield in the book edited by Blahd (Greenfield 1965). A pithy summary of the development of radiation dosimetry, with examples involving both external sources and radionuclides in tissues, is given by Quimby as the first chapter in an Atomic Energy Commission (AEC) symposium held at Oak Ridge in 1969 (Quimby 1970).

The system was applied early to the beta particles from ^{32}P . It involved development of a unit for tissue absorption to be the equivalent of 1 roentgen of x rays in air (Marinelli, Quimby, and Hine 1948). This was called the equivalent roentgen (e.r.).^(b) It was calibrated in terms of the necessary number of beta particles of a given average energy needed to produce the same amount of ionization in 1 g of tissue as is produced by x-ray photons delivering 1 roentgen in air. Obviously, to obtain the total number of beta particles released per unit volume of tissue, it was necessary to know the kinetics of both physical decay and biological elimination, tissue distribution, etc. We saw instances of the importance of these and other parameters in chapter 16 and noted the fact that the numbers had been provided largely by the radioisotope toxicology people.^(c)

(a) *Note added in proof:* In the interim between completion of this chapter and publication of the book, the National Council on Radiation Protection and Measurements issued a report (NCRP 1985a) that includes a careful review of some of the history reviewed in the following pages. It is, in some ways, more sophisticated, in that it ties the internal dosimetry procedures more overtly to the practices developed for measuring external radiation, particularly radium gammas. The chairman of this committee was James S. Robertson, Department of Energy (DOE), whose role is mentioned briefly in the text that follows herein. If this report had been available when this chapter was written, the dosimetry section could have been somewhat shorter. Nevertheless, there is only a modicum of undesirable overlap between the two documents.

(b) This is very similar to the “rep” or “roentgen equivalent physical,” which Parker developed at Hanford during the MED days. This had to await declassification to be known widely in the medical area (see Parker 1950), and the “e.r.” designation was used meanwhile by Marinelli et al. The rep was actually used much more in subsequent years. See Evans (1948) for conversion of reps to absorbed doses in tissues and more on its use.

(c) Very useful handbooks were produced within the government-supported laboratories that made the handling of radioisotopes and the calculation of doses considerably easier. A very early document to the open literature was a table of isotope decay prepared by Bruner, King, and Smyser (1951). Later, the Bureau of Radiological Health of the U.S. Public Health Service (PHS) produced its *Radiological Health Handbook* largely as a training aid that became a basic reference and major resource in the health field (see BRH-NTIS 1970). These and numerous others, plus the reports of the ICRP, NCRP, and MIRD have provided invaluable source material in usable form. A basic table of isotopes was produced even earlier by Seaborg and Perlman (1948).

The principles and how the equations got reduced to fairly simple shorthand renditions are well depicted in the chapter on dosage calculations for radioactive isotopes in the monograph by Quimby and Feitelberg 1963). This system was the basis of the formulations in Publication 2 of the International Commission on Radiological Protection (ICRP 1959). Partly because of this step and partly because of the development of a system for gamma emitters by the same group, which was used for many years, what is termed here "The Classical System" was historically called "The Marinelli System," sometimes the "ICRP System," and sometimes the "Marinelli-ICRP System."

Illustrations.^(a) The system was quite simple in cases where the radiation arose from sources such as alpha emitters, relatively low-energy beta emitters, or from other sources with short path lengths in tissue. It was assumed that distribution of the radioisotopes was uniform within the organ, that the organ was homogeneous, and that all energy was absorbed within the organ or tissue.

1. Dose rate from nonpenetrating radiation.^(b)

$$\text{Rads/day} = \frac{(\text{d/min}/\mu\text{Ci}) \times (\text{min/day}) \times (\bar{E} \text{ in MeV/day})}{\text{weight of organ} \times \text{MeV/100 ergs}} \times C_0$$

where C_0 = initial concentration of activity in the organ or tissue

\bar{E} = average energy in MeV/disintegration

1 erg = 6.25×10^{11} eV

100 ergs = 6.25×10^{13} eV

1 rad = 100 ergs/g = 6.25×10^7 MeV.

If we are interested in daily dose, and *there is no appreciable loss of activity during one day*, the above can be shortened to $51 C \bar{E}$ where $C = \mu\text{Ci/g}$ and \bar{E} = average energy.

The answer is in rad if the energy term refers to physical energy alone, but in rem if the energy term has been corrected for the relative biological effectiveness (RBE) of the radiation emitted (in which case it is called "effective energy").^(c)

(a) These illustrations were developed in part by Dr. John Hursh and this author in a course given at the University of Rochester and do not rigorously follow the symbols and formulations of Marinelli (1942) or Marinelli, Quimby, and Hine (1948), but they use the same principles.

(b) Does not penetrate beyond the source organ (organ of deposition).

(c) The expression for effective energy has undergone several changes with time. In the earlier formulations, it was the sum of the physical energy (average), times a factor F to account for the ratio at time t of disintegrations from any daughter products that remain in the target organ to the disintegrations of the parent, the RBE and a factor n , which applied to bone seekers and reflected their relative toxicity as we discussed in much detail in chapters 7, 8, and 16. In later formulations, the term RBE was replaced by the Quality Factor (QF or Q) to reflect the fact that it was an arbitrary number based on linear energy transfer and might or might not represent the actual RBE in a given biological system. In still later formulations, to be discussed in a later section, the entire term became "Specific Effective Energy" (SEE). When these modifying factors are used, the unit of the final answer is the "rem" whose origin has an interesting history (Parker 1981). It can be translated as "roentgen-equivalent man" or "roentgen-equivalent mammal" if need be.

2. Total dose, assuming energy absorption is totally within the organ of interest.

$$D_{\text{(rads)}} = \frac{C_0 \times (\text{d/min}/\mu\text{Ci}) \times \bar{E} \times 1.44 T_e \times \text{min/day}}{\text{weight of organ} \times 6.25 \times 10^7 \text{ MeV/g/rad}}$$

where $C_0 = \mu\text{Ci}$

\bar{E} = Average energy (effective)^(a)

T_e = effective half-life in days (see attached derivation).

This is sometimes shortened to:

$$D = 73.8 C \bar{E} \tilde{T}_e (1 - e^{-\lambda_e t})^{(b)}$$

if C_0 is in microcuries, and half-lives are in days.

The expression \tilde{T}_e refers to the mean lifetime ($1.44 \bar{T}_e$), whose derivation is given in a separate section below. The decay constant λ_e is the effective decay that includes both radioactive decay and biological loss.

3. Effective half-life—Radionuclides are lost from the body by two processes: physical decay and biological loss,^(c) mainly excretion.

It is convenient to assume that the latter is first-order with respect to time, similar to radioactive decay. Thus, we can express biological loss rate as:

$$-\frac{dN}{dt} = \lambda_b N$$

and total loss as:

$$-\frac{dN}{dt} = (\lambda_p + \lambda_b) N$$

where N = no atoms

λ_b = biological loss constant

λ_p = physical decay constant

We can combine $(\lambda_p + \lambda_b)$ into λ_e , the effective loss constant.

$$\text{Biological half-life} = T_B = \frac{0.693}{\lambda_b}$$

$$\text{Effective half-life} = T_E = \frac{T_p T_B}{T_p + T_B}$$

where T_p is the physical half-life.

(a) See footnote (c) on previous page.

(b) The constant 73.8 is the product $(3.7 \times 10^4 \text{ dis}/\mu\text{Ci}/\text{sec})(1.6 \times 10^{-6} \text{ erg}/\text{MeV})(10^{-2} \text{ rad}/\text{erg})(86,400 \text{ sec}/\text{day}) 1/\ln 2$.

(c) In some older literature, the term "biological loss" represented total loss and what has been called biological loss above was called "excretion loss," with symbols suitably confusing. This did not last long, but may be encountered in early papers.

4. Mean lifetime—We cannot use the half-life concept to find total number of atoms disintegrating, because half-life is a statistical concept. Any given atom might disintegrate anytime from now to infinity. To have a useful figure, we must use an expression called “mean” or “average” lifetime.

The number of atoms breaking up in interval t to $t + dt$ is

$$\lambda N_t dt \text{ or } \lambda N_0 e^{-\lambda t} dt.$$

The total lives of all these atoms added together is the total number times the life of each or

$$\lambda t N_0 e^{-\lambda t} dt$$

or the integral from 0 to ∞ of the totality of atom lives divided by N_0 (the original number of atoms).

$$\begin{aligned} \text{Av. life} &= \frac{1}{N_0} \int_0^{\infty} \lambda N_0 t e^{-\lambda t} dt \\ &= \left[-te^{-\lambda t} - \frac{1}{\lambda} e^{-\lambda t} \right]_0^{\infty} = 0 + \frac{1}{\lambda} \end{aligned}$$

$$\frac{\Sigma \text{ all lifetimes (atom years)}}{\text{Total number of atoms}} = \frac{N_0}{\lambda N_0} = \frac{1}{\lambda}$$

$$\bar{T} = \frac{1}{\lambda} = 1.44 T$$

$$\text{Since } \lambda = \frac{0.693}{T}, \frac{1}{\lambda} = \frac{T}{0.693} = 1.44 T$$

5. Still considering situations where all of the energy is absorbed in the organ containing the radionuclide, it is also possible to formulate a calculation for the dose over a given interval of time, but this carries us beyond the purposes of this short historical review. It can be seen in cited reviews.

6. Penetrating radiations—With photon rather than particulate radiation, the assumption that all of the energy is absorbed in the organ of interest will usually be incorrect. Also, the calculation of absorbed dose in organs from a gamma-ray source external to the body could not be done on the same basis as the exposure dose used for x rays. Much of classical dosimetry for radioisotopes grew up around these problems.

The approach for radionuclides within the body can be illustrated by an excerpt from the chapter on dosage calculations for radioactive isotopes in the text by Quimby and Feitelberg (1963):

Gamma Ray Emitting Nuclides in the Body. In the case of gamma rays emitted within an organ or anywhere within the body, absorption is rarely complete within the tissue of interest. The approach to the dosage problem must therefore be different from that for beta rays.

When the nuclide is distributed throughout a volume of tissue such as V [see figure 20.1] . . . with a concentration of C μCi per gram, the dose rate per hour at any point P due to the quantity of radionuclide CdV present in a small volume at a distance r from P will be

$$d(dy) = \frac{10^{-3} \Gamma C e^{-\mu r}}{r^2} \text{ roentgens per hour,}$$

[The symbol Γ is the "specific gamma ray constant" in units of $\text{R/hr-per unit of activity at 1 cm.}$]

where μ is the *effective* absorption coefficient of the radiation per centimeter of tissue. The value of this absorption coefficient depends on the fraction of the scattered radiation which is absorbed within the tissue. Its evaluation is very complicated, but fortunately, for absorption in unit density material it is essentially constant, and less than 0.03 cm^{-1} for gamma ray energies in the range from 0.1 to 2.0 Mev. (The dose rate for $1 \mu\text{Ci}$ at 1 cm is $10^{-3} \Gamma$.)

The total dose rate at point P then is

$$dy/(\text{hr}) = 10^{-3} \Gamma C \int_V \frac{e^{-\mu r}}{r^2} dV \text{ roentgens per hour.}$$

This expression is not readily integrated except when the volume is a sphere, but it can be evaluated for some other shapes. It may be called the *geometrical factor* and represented by g . In any volume the value of g will depend on the position of the point of reference, being a maximum at the center and a minimum at the surface. Usually what is desired is an average gamma dose rate, and for this purpose it is desirable to define an average geometrical factor, \bar{g} . For a sphere of unit density material, of radius R ,

$$\bar{g} = 3\pi R, \text{ for radii up to 10 cm.}$$

The total gamma ray dose, Dy , is . . . $dy/(\text{hr})$ multiplied by the average life in hours:

$$Dy = 10^{-3} \Gamma C \bar{g} \times 1.443 \times 24 T = 0.0346 \Gamma C T \bar{g} \text{ roentgen,}$$

[The constant 0.0346 is the product of $(10^{-3}/\mu\text{Ci})(24 \text{ hr/day})$ and $(1/\ln 2)$.]

where T is the half life in days.

(Quimby and Feitelberg 1963, pp. 116-118)

Clearly, the fact that gamma ray attenuation is exponential means that the fraction of energy absorbed within a tissue or organ will never quite reach 1, although it may approach 1 closely.

Comment on the Classical System. The above represents more than the original Marinelli concept and formulation. There has been much extension to include work done by the committees of the ICRP and NCRP (see chapter 16) and others in the toxicology and radiation protection fields.

Many of these extensions came first from work in the MED.^(a) Obviously, those concerned with setting of exposure standards had to work in the war years under the security restrictions of the MED. They developed systems for immediate application to radiation protection (i.e., health physics). Postwar publication of these showed the extent and elaborateness of their work. It went

(a) See earlier chapters.

FIGURE 20.1. Basis for calculation of dose rate (see text) from gamma-emitter distributed through large volume of tissue. (Redrawn from Quimby and Feitelberg 1963. Reprinted with permission of Lea and Febiger, Philadelphia, Pennsylvania, copyright 1963.)

far beyond the original "classical" system in its application to radioisotopes (Morgan 1947; Cohn 1948). The calculations were extended to exposition of maximum permissible body burdens and maximum permissible concentrations of radionuclides in air and water for occupational exposure, as we saw in chapter 16. They can be seen in the reports of the ICRP (1959) and the NCRP (1959). Other expositions can be found in Hine and Brownell (1956), which contains several review papers; Reports 10a and d of the International Commission on Radiation Units and Measures (ICRU 1962a,b); Spiers (1968), especially chapter 3; Mayneord (1950); Morgan and Turner (1973), especially chapter 10 by W. S. Snyder (Snyder 1973); and the various textbooks of health physics.

As formulated, the system most widely used in radiation protection was locked into the concept of continuous intake and limitation of exposure to a critical organ or tissue. Later it was redone to accommodate single rather than continuous intake. However, the end result was still aimed at the maximum allowable burden or permissible exposure.

Physicians wishing to calculate the dose to their patients could do so using rule-of-thumb formulations. However, it was very difficult to calculate the dose to one organ from radionuclides deposited in another without making many unduly simplifying assumptions. Frequently, more than one type of irradiation was emitted by the deposited radionuclides. Body organs are irregular in shape and far from homogeneous, despite the assumptions made. The assumption of uniform distribution bothered many, since distribution is seldom uniform. Also, the assumption of a single exponential function of time to describe retention (i.e., the single effective half-life) was frequently only a convenient fiction. In some organ complexes, build-up of secondary radiations had to be accounted for as a function of distance from the source. Also, nuclides emitting both beta and gamma radiations required separate calculations.

None of these problems was insoluble with the classical system. Indeed, starts were made on all of them. We can see examples in the chapter by Snyder (1973) and by Saenger and Kereiakes (1971). Nevertheless, preoccupation^(a) of the classicists with radiation protection situations and the growing complexity of

(a) Probably more perceived than real.

their operations led those working in nuclear medicine to feel they had to devise a scheme more responsive to their perceived needs.^(a)

B. The MIRD System

In November 1965, Edward M. Smith, a physical scientist on the staff of the Hospital for Special Surgery affiliated with the Cornell University Medical College in New York, delivered a paper at the Oak Ridge symposium on radioactive pharmaceuticals (Smith 1966) that discussed the various problem areas of absorbed-dose calculations when applied to pharmaceuticals rather than inorganic salts. This paper stressed the lack of good biological information on the behavior in vivo of radioactive pharmaceuticals. It served to encourage the further development of an independent approach to internal dosimetry and attracted the support of the Society of Nuclear Medicine. As such things always do, it led to the formation of a committee, the "Medical Internal Radiation Dose" (MIRD) Committee of the Society of Nuclear Medicine. A group had been organized in 1964, and, from 1965 on, it went all out for a comprehensive system tailored to medical (i.e., clinical) problems and uses. A series of papers published for the most part in the *Journal of Nuclear Medicine* were bound together as pamphlets (called MIRD pamphlets), the first being issued in February 1968.

Smith moved to the University of Miami soon after the Oak Ridge meeting, and he became the first cochairman and then executive director of MIRD. Smith explains the basis for MIRD as an introduction to pamphlets 1, 2, and 3. Excerpts are given below.

In October 1964 the president of the Society of Nuclear Medicine, John Hidalgo, initiated an ad hoc committee of the Society to serve the needs of nuclear medicine in the determination of the radiation absorbed dose to patients who are administered radiopharmaceuticals. An active group within the Society agreed that data and information available to the profession at that time were not adequate to determine to the desired accuracy the absorbed dose resulting from the use of radioactive materials in diagnostic studies.

The tissue distribution data relating to biologically-distributed radionuclides had been gathered primarily for the purpose of establishing health safety standards for workers exposed to elemental forms of the radionuclides rather than for specific chemical forms (radiopharmaceuticals). There existed established techniques for determining the absorbed dose delivered by external or by encapsulated interstitial radiation sources for therapeutic purposes, but the data needed to calculate internal radiation absorbed dose due to biologically-distributed radiopharmaceuticals with the degree of confidence that physicians preferred were scattered and not easily available. Also there was doubt that the data were the best that could be generated in view of new developments in nuclear spectrometry, computerized absorbed-dose computation techniques and improved measuring techniques for determining the tissue distribution and life-times of radiopharmaceuticals in patients. In addition, the increase in the use of radionuclides that emit low-energy photons presented some serious problems to the accepted methods of calculating the absorbed dose.

Mr. Hidalgo, with the encouragement of C. Craig Harris, organized the committee with Drs. Monte Blau and Edward M. Smith as co-chairmen. Both were active in

(a) A report by ICRP, *Protection of the Patient in Radionuclide Investigations* (ICRP 1971), addressed the physicians' problems, perhaps somewhat belatedly, and, unfortunately, it did so in a nonquantitative manner.

the search for better and more reliable methods of estimating the absorbed dose to patients resulting from the diagnostic use of radionuclides. Dr. Blau assumed direction of the branch of the committee concerned with biological data, and Dr. Smith headed a team primarily concerned with the physical aspects of the problem.

The objective of the committee, stated at its first meeting, was and still is:

To provide the best possible estimate of the absorbed dose to patients resulting from the diagnostic or therapeutic use of internally administered radiopharmaceuticals with the restriction that the committee make no judgment as to the medical significance of the estimated absorbed dose.

In order to achieve the above objective, the committee has proposed to develop, collect and critically evaluate information in the following areas:

1. Formulae, units and symbols that are consistent for absorbed-dose calculations by either manual or computer techniques.
2. Physical and nuclear decay-scheme data needed as input for the formulae developed.
3. Metabolic data on the distribution and life-times of radiopharmaceuticals at the total-body, specific-organ, sub-organ and micro-organ level where necessary as well as the influence of the patient's age and clinical state on these variables.
4. Chemical, radiochemical and radionuclidic purity and stability and physical characteristics of radiopharmaceuticals when they are apt to affect the absorbed dose to the patient.
5. Accuracy of the calibration methods used for determining the activity of a radiopharmaceutical.
6. Anatomical and physiological data for patients of various ages and body types.

In the fall of 1965 the Society was awarded a grant by the National Center for Radiological Health of the U.S. Public Health Service (at that time the Division of Radiological Health) to support the work of the committee.

Since the beginning of 1967 the committee has been actively working with the Food and Drug Administration in the evaluation of absorbed dose and other related areas. Efforts are being made to establish a master file of biological data and absorbed-dose calculations that will be deposited with the Food and Drug Administration and made available to the radiopharmaceutical manufacturers as an aid in preparing their package inserts. Representatives of the radiopharmaceutical industry were invited to attend the June 1967 committee meeting as observers. (Smith 1968)

A list of the membership of MIRD between its formation and the issuing of the first pamphlets is given below.

Members of the Medical Internal Radiation Dose Committee (1964 to 1968)

Cochairmen

Edward M. Smith, University of Miami
Monte Blau, Roswell Park Memorial Institute

Secretary

Jonathan P. Miller, Abbott Laboratories

Members

Martin J. Berger, National Bureau of Standards
Mones Berman, National Institutes of Health
Gordon L. Brownell, Massachusetts General Hospital
Karin R. Corey, Memorial Hospital for Cancer and Allied Diseases
William H. Ellett, Royal Postgraduate Medical School, London

R. Eugene Johnston, Vanderbilt University
 Katherine A. Lathrop, University of Chicago
 John S. Laughlin, Sloan-Kettering Institute
 Robert Loevinger, International Atomic Energy Agency
 John McAfee, State University of New York
 Kenneth R. McCormack, Saroni Tumor Institute
 Richard Peterson, University of Iowa
 James S. Robertson, Brookhaven National Laboratory
 Robert H. Rohrer, Emory University
 Henry N. Wagner, Jr., The Johns Hopkins University
 Henry N. Wellman, Robert A. Taft Sanitary Engineering Center

Others who helped in the early stages were Robert Greenlaw, University of Kentucky; C. C. Harris, Oak Ridge; J. Krohmer, Roswell Park; G. Leudenblad, E. R. Squibb and Sons; and Jonathan Miller, Abbott Laboratories, who stayed on as secretary. As the work went forward, Smith became executive director; Rohrer, chairman; and Blau, vice-chairman. Ellett moved to Oregon State University. Walter Snyder of Oak Ridge, already the dean of Internal Dosimetry^(a) from the radiation protection standpoint, got interested and contributed greatly to the newer formulations, and Thomas Dillman of Ohio Wesleyan University (earlier Oak Ridge) joined up to bring his expertise in radionuclide decay schemes and nuclear parameters.

There can be no question about the breadth of representation in MIRD from the standpoint of both disciplines and institutions. Yet, key roles were obviously played by "old pros" such as Blau, Brownell, Loevinger, Robertson, Snyder, and Wagner, with Smith's enthusiastic leadership.

Abbreviated subjects and a list of the authors of the first nine pamphlets are given below. They are included in the references to this chapter.

Pamphlet

1. Schema; Loevinger and Berman (1968)
2. Energy Deposition in Water; Berger (1968)
3. Absorbed Fractions; Brownell, Ellett, and Reddy (1968)
4. Decay Schemes; Dillman (1969)
5. Absorbed Fractions; Snyder, Ford, Warner, and Fisher (1969)
6. Decay Schemes, Part 2; Dillman (1970)
7. Distribution of Absorbed Dose; Berger (1971)
8. Absorbed Fractions for Small Volumes; Ellett and Humes (1971)
9. Absorbed Dose from Radionuclides; Atkins, Robertson, Croft, Tsui, Susskind, Ellis, Loken, and Treves (1980)

Perusal of the titles for the first eight pamphlets indicates a depth of treatment of physical aspects quite beyond that expected from an enterprise trying to rectify only problems with medical aspects of dosimetry. It was a major research undertaking. There are those, and some are within the nuclear medicine fraternity, who feel that some of the effort was more for the promotion of nuclear medicine as a separate viable discipline than to solve the problems outlined in the prelude to the first pamphlets. But this does not detract from the validity of the system developed.

(a) Called "Mr. Internal Dosimetry" in his citation for the Distinguished Achievement Award of the Health Physics Society in 1975.

The ninth pamphlet concerns the specifics of radioxenons. Later pamphlets went back over some of the same ground and included detailed information for decay schemes for medically important radionuclides, the absorbed dose (S) per unit of cumulated activity for selected radionuclides, kinetic models, etc. Some of these were close to, indeed part of, the system described in the next section.

We will not cast judgment on whether or not it could have been done an easier way and the research talent applied elsewhere. Instead, let us look at the primary features of the MIRD system.

In a simplified version written by Cloutier, Watson, and Coffey (1978) for a text book of nuclear medicine, the MIRD formulation looks as follows:^(a)

$$\dot{D} = k \cdot \frac{A}{m} \cdot E$$

where \dot{D} = the absorbed dose per unit time
 k = a constant whose value depends on the units used for the other factors in the equation
 A = the amount of activity
 m = the tissue mass so that A/m is the activity per unit mass
 E = the average energy released per transformation.

If \dot{D} is expressed in rads per hour, A in microcuries, m in grams, and E in million electron volts per nuclear transformation, the constant k is 2.13 and the dose rate equation becomes

$$\dot{D} = 2.13 \frac{A}{m} E.$$

Because the average energy released per transformation, E , is a constant for each radionuclide, the two constants, k and E , may be combined into one constant, Δ .

$$\Delta = 2.13 E.$$

Hence,

$$\dot{D} = \frac{A}{m} \Delta.$$

In reality, a Δ value exists for each type of radiation: β^- , β^+ , γ , etc.

This concerns equilibrium absorbed dose for uniformly distributed radionuclides and a finite homogeneous medium (Δ is the equilibrium absorbed dose constant) and assumes there are no boundary effects. When the attempt is made to extend to general situations, a much more complex-appearing formulation is generated.

First we should consider the adoption of the absorbed fraction concept. This has already been alluded to and was used in some of the later versions of the classical scheme. However, it was applied in full for the MIRD formulation. Sometimes called the Loevinger-Berman formulation, it generalized from a formulation introduced into gamma-ray dose calculations by Ellett, Callahan, and Brownell (1964). It represents the fraction of the energy emitted in a source organ that is absorbed in the target organ. (Sometimes these may be one and the same, and the absorbed fraction is then 1.)

(a) Good, somewhat simplified descriptions of the MIRD scheme are given by Cloutier and Watson (1973), as well as by Cloutier, Watson, and Coffey (already cited), but those interested in the whole story must go to the MIRD pamphlets.

Single absorbed fractions are symbolized by d , while the specific absorbed fraction is defined as

$$\phi = \frac{\phi}{m}$$

Note that the specific absorbed fraction is simply the absorbed fraction per unit mass.

When all the components are put together, a single equation can be generated to cover dose or dose rate from any source of activity to any target for all types of radiation. Loevinger represents this as follows:

$$\bar{D}(r_1 \leftarrow r_2) = \bar{A}_2 \sum_i \Delta_i \phi_i(r_1 \leftarrow r_2) \quad \text{Upper arrow (3a)}$$

$$\text{Lower arrow (4a)}$$

The symbol \bar{D} indicates that the equation gives the mean dose. The argument of \bar{D} is $r_1 \leftarrow r_2$, which indicates that the mean dose is that given to target region r_1 from source region r_2 . Since the definition of a region includes points, lines, surfaces, and volumes, it follows that the equation applies to any source and any target. The left side of the equation can be read as "the mean dose to region r_1 from region r_2 ."

The symbol \bar{A}_2 represents the cumulated total activity in region r_2 during the relevant time interval. The activity A_2 , of which \bar{A}_2 is the integral, can be distributed in region r_2 in any manner, i.e., the equation does not assume a uniform distribution of activity in the source region. . . It is now apparent that \bar{D} is the spatial mean dose in the target region during the time interval over which the activity has been integrated.

Equation 3a is quite general, containing no assumptions about the distribution of the activity or the nature of the absorbing material. The term $\phi_i(r_1 \leftarrow r_2)$ can be read as "the specific absorbed fraction in target region 1 from source region 2." Although this equation is always valid, there may be some difficulty in obtaining numerical values for $\phi_i(r_1 \leftarrow r_2)$ for a nonuniform distribution of activity in the source region r_2 .

Equation 4a applies only when the reciprocity relation (originally due to Mayneord) is valid. Then the term $\phi_i(r_1 \leftrightarrow r_2)$ can be read as "the specific absorbed fraction in r_1 from r_2 , or in r_2 from r_1 ." The double-ended arrow in fact represents the entire reciprocity relation, which in its most general form simply says that the specific absorbed fraction is independent of which region is designated source and which is designated target. (Loevinger 1970)

After some further explanations, Loevinger goes on as follows:

We are now in a position to recognize that the general dose equation is not a forbidding and mysterious thing but is just a common-sense way of expressing the absorbed dose. To see this let us write Eq. 3a for a single radiation type:

$$\bar{D}_i(r_1 \leftarrow r_2) = \bar{A}_2 \Delta_i \phi_i(r_1 \leftarrow r_2)$$

Since Δ_i is the emitted energy per disintegration and ϕ_i is the fraction of this energy absorbed per unit mass in the target region, the product $\Delta_i \phi_i$ must be the i -type energy absorbed per unit mass per disintegration in the target region. Multiplying this product by the number of disintegrations, \bar{A}_2 , gives the i -type energy absorbed per unit mass in the target region, i.e., the mean dose from i -type radiation. To obtain Eq. 3a, it remains only to sum over all radiation types.

Thus we see that the concept of specific absorbed fraction allows formulation of a simple, easily understood equation which includes all possible sources and targets and radiations and which may exclude or include the reciprocity relation by a small change of notation (single-ended to double-ended arrow). Note particularly that this degree of generality was not possible until the specific

absorbed fraction was introduced. This one concept at a single stroke unified the entire field of internal-dose calculation into a single equation.

And later on the author states:

Equations 3a and 4a can, of course, be written in simpler forms for particular purposes. Certainly they appear much less forbidding if written simply as

$$\bar{D} = \bar{A} \sum \Delta_i \Phi_i$$

(Loevinger 1970)

Quite obviously, one does not undertake such generalized all-inclusive calculations with a simple old-fashioned desk calculator. Another prime contribution of the MIRD work was the use of the computer-based Monte-Carlo method. Whereas a manual method was possible as described by Snyder (in Morgan and Turner 1973, especially page 312) by utilizing "first-interaction" calculations with averages rather than probabilities, the Monte-Carlo system uses a scheme based on random numbers through which one can select a value of an indeterminate variable to use in a given calculation.^(a)

A final advance introduced by the MIRD approach was the very liberal use of phantoms to represent body organs or even the whole body at different ages. These are used both experimentally and as mathematical models. The experimental phantom is constructed of material that simulates living tissue in atomic composition (i.e., is tissue equivalent) and simulates also the shape, size, and relative location of body organs. Sometimes they are hollow plastic shells, which can be filled with a radioactive solution or with a discrete source, and measurements can be made at various distances and in different configurations. There are also models of each important organ. These go far beyond the convention of the classical system with its spherical model and with the radio-nuclide uniformly distributed therein.^(b,c)

The mathematical organ models are given in detail by Snyder et al. (1969) and Snyder (1970) and by Cloutier, Watson, and Coffey (1978). They look sufficiently like surrealistic paintings of the Salvador Dali school to make anyone feel very modern. But they have served their purpose well. The phantoms (models) for standard man and child are robot-like in appearance. The reference-man phantom, showing some internal organs, is presented well in the paper by Cloutier, Watson, and Coffey (1978) and is reproduced as figure 20.2.

FIGURE 20.2. Reference-man phantom showing some internal organs. (Redrawn from Cloutier, Watson, and Coffey 1978. Reprinted with permission of Lea and Febiger, Philadelphia, Pennsylvania, copyright 1963.)

- (a) It is somewhat surprising that the introduction of this highly sophisticated, almost occult set of manipulations did not scare away the physicians. Evidently they were convinced not to flinch by the many other contributions of computer science to medicine.
- (b) Similar phantoms were used for years in x-ray dosimetry and could as well have been applied in the "classical ICRP" system for internal dosimetry. Indeed, they were to some extent.
- (c) Further details concerning these phantoms and models, especially the pediatric models, and including pictures as well as diagrams, appear in the NCRP report cited above (NCRP 1985c.)

Obviously, the MIRD schema introduced entirely different symbols for the key quantities, even those closely similar to the Marinelli-Quimby-Hine system. This has resulted in the MIRD system seeming more different from the classical one than it is. (The development of an entirely new symbolism seems to be irresistible to any committee engaged in developing a major revision of any system involving mathematical formulations.) The summaries by Cloutier and colleagues already cited give the details. Robertson (1981) has related the classical gamma dose formula to the MIRD formula by first expanding the various factors into their component parts and then regrouping them.^(a) He also points out those factors that are not interconvertible because they were developed by quite different methods. The doses calculated by the two methods are usually in close agreement, it may be added.

Before we consider further details, we should list a few of the advantages of the MIRD schema as enumerated by Loevinger:

1. It applies to all types of radiations without exception. As a result, no arbitrary categories are imposed on the radiation types.
2. It applies to all source regions and all target regions, i.e., to points, lines, surfaces, and volumes.
3. Dose and dose-rate equations are the same except for a simple change of symbols. The emitted energy per disintegration, Δ_i , depends only on the radionuclide considered.
4. The schema separates the physical and biologic factors in a clean and convenient manner. For the usual case, when the assumed organ size and distribution of activity do not change with time, the activity A (or the radioactive concentration C) contains all the time-dependent terms, such as the physical and biologic half-lives. The emitted energy per disintegration Δ_i contains not only the mean energy per disintegration but also the conversion factors for the chosen units. The specific absorbed fraction Φ_i (or the absorbed fraction ϕ_i) contains the information on the distribution of the absorbed energy from the source.
5. The absorbed fraction ϕ is often a convenient parameter. It is bounded by zero and unity, and, as a result, it is often possible to make a common-sense estimate of ϕ with adequate accuracy. The value of ϕ is insensitive to the size and shape of the target volume when $\phi \approx 1$. The ϕ 's add when combining target volumes.

These are but a few of the listed advantages. Loevinger goes on to say:

For some, one disadvantage of the method of internal-dose calculation that I am describing is its unfamiliarity. To become familiar with it, a person must devote considerable time to mastering it, and that time can be justified only if the new method offers significant advantages over the old. Obviously I believe this to be true because otherwise I would not presume to advocate the new method. (Loevinger 1970)

C. The Snyder-Modified ICRP System

The fact that Walter Snyder, Oak Ridge National Laboratory (ORNL), was enlisted into and became deeply interested in the MIRD enterprise, as mentioned earlier, brought about a very important confluence of the two systems. Snyder recognized that the deficiencies in the original classical system, outlined above, applied also to the calculations for radiation protection purposes and

(a) This maneuver by Robertson has as many arrows as a complex football-play diagram and attests to the extent of the differences. Nevertheless, the fact that it is possible indicates there are basic similarities.

occupational exposures. Over a period of several years, he and the Oak Ridge Internal Dosimetry group developed a very complete new system of dosimetry calculations using in part his contributions to the MIRD. Since he already had the data bank of physical and biological "constants" used for ICRP and NCRP reports and could modify them in the light of new information turned up in the MIRD activities, he could stimulate a comprehensive development. Colleagues in this enterprise were Mary Rose Ford, who has been identified with internal dosimetry since the time when K. Z. Morgan chaired the Internal Dose Committees of both ICRP and NCRP and who preceded even Walter Snyder into the field; Karl Morgan, especially in the decade of the sixties; John W. Poston, a bright young physical scientist at the Georgia Institute of Technology;^(a) G. G. Warner, S. B. Watson, S. F. Deus, and V. Provenzano, all at ORNL at the time. Associated, but more or less independent, was S. R. Bernard, ORNL.

Some of this work went in parallel with the developments of Ellett and coworkers in the MIRD enterprise, already cited. (Representative references are: Snyder and Ford 1965; Snyder, Ford, and Warner 1968; Snyder et al. 1975a,b,c; Snyder, Ford, and Watson 1975; Snyder et al. 1976; Snyder 1970; Ford, Snyder, and Warner 1975; Deus and Poston 1976; and Deus, Provenzano, and Snyder 1977.)^(b)

A corollary to the absorbed fraction as used in MIRD is an entity derived from it and applicable to the final results called the "S" value. This was introduced by Snyder and perhaps the "S" can be traced to his name. It represents the absorbed dose per unit of cumulated activity, i.e., rad/ μ Ci-hour.

Since this system was much more likely to be applied to materials of long physical and/or biological half-lives than the MIRD system, factors for retention kinetics were necessary. It was possible to utilize the long experience with radioisotopes in the body and introduce retention equations with much more than a single exponential. These could be tailored to the period over which the calculation was desired and worked into the concept of dose commitment described by the ICRP (ICRP 1979) as related in chapter 16 and commented upon by NCRP (1985a).

The system was developed to apply more to radiation protection activities than to medical doses as such and to this extent works best for a population of adults. Inaccuracies will occur if it is applied to individual patients whose physical and physiological characteristics may differ from the models and phantoms used. Since it is unrealistic to construct a special phantom for each patient, a system of scaling factors has been started, but it is clear that such a system cannot be simple.

The result can be seen as ICRP Publication 30 (1979) and its voluminous appendices which give "S" factors and other derived figures such as annual limits for intake and derived air concentrations for over seven hundred radionuclides and a large variety of source and target organs. (The NCRP is now busy adapting the main features of the system to U.S. practices; see NCRP 1985a.)

(a) At Oak Ridge in the earlier years and moved recently to Texas A&M University.

(b) The assembly of these and many other references used in this section was aided greatly by use of a draft NCRP report prepared by J. S. Robertson (formerly Mayo Clinic, now DOE) and NCRP Scientific Committee-55, recently published as NCRP report No. 83 (NCRP 1985c).

Since this was all an outgrowth of the activities of Snyder and his associates, it seems appropriate to call the system the "Snyder-Modified ICRP System" or "Snyder System" to honor Walter Snyder's memory.

The work has been carried forward since Dr. Snyder's untimely and unfortunate death in 1977 (for obituary see *Health Physics*, Vol. 34, No. 1, January 1978) by many of his former associates, particularly Troyce Jones, John Poston, and, of course, Mary Rose Ford, and by more recent additions, J. M. L. Hwang and Keith Eckerman.

Comment. The MIRD and Snyder Systems can be regarded as major contributions of nuclear medicine to radioisotope toxicology to the degree that standard setting and radiation protection are closely related to the toxicology enterprise and also as an interaction in the other direction.

Yet, the task is far from completed. On the nuclear medicine side, it is frequently necessary to idealize the patient and his health status to an undesirable extent. We need easier ways to go from the general to the specific. (Desk-top computers in nuclear medicine departments are already beginning this.) We still need much more information on the true spatial distribution of radionuclides within source organs. We are still undecided about the true target cells in many situations and will be until the mechanisms of carcinogenesis and other biological processes are further elucidated.

On the radiation protection side, we have less reason to tailor the calculation to a particular individual except for evaluation and assessment of significant over-exposures. But we are in need of much better models for different ethnic groups, different age groups, and the effect of physiological and biochemical abnormalities. We have only one fully developed model for metabolism of radioisotopes in a tissue, viz., bone, as seen in chapter 16.

Naturally, the nuclear medicine people usually find the MIRD system appealing, especially because of the assemblage of data covering radiopharmaceuticals and thus direct pertinence to their operations. For the same reason, most workers in radiation protection use or plan to use, with modifications, the Snyder-Modified ICRP scheme. Yet, some workers in nuclear medicine—not necessarily old conservatives—lean toward the classical system, while many health physicists teach and use the MIRD system.

The extent to which the final answers obtained by the two systems are comparable was illustrated by Snyder (1973) with estimates of absorbed fractions. He compared the manual ICRP (the classical ICRP not the Snyder-Modified ICRP) and the Monte-Carlo methods. The results are shown in table 20.1.

The figures are not identical and show a progression in their ratio from about 0.9 to 1.39 (ICRP/Monte Carlo) with increase in energy. The larger differences, almost 40%, occur in high-energy regions of more application to radiation protection and toxicologic dose calculations than to medical uses. The final answers are not changed as much as these absorbed fractions.

It is obvious that the efforts put into internal dosimetry have been of considerable magnitude and involved much research talent. They have occupied some excellent minds full-time and a gifted cadre of people who were good at calculations and later at computer operations, and who could also sift an enormous mass of physical and biological information to insert the best estimates for a given function (chapter 16).

Despite the considerable input from the nuclear medicine side, a large share of the daily sweat came from the brows of people supported in the major

TABLE 20.1. Estimates of the Absorbed Fraction for Total Body (70 kg)

internal emitter toxicology groups—on both sides of the Atlantic—whom we have met earlier in this book. Thus, the effort must be set down as an important product of governmental support for both the experimental and computational programs. We would have no decent standards or proper medical controls without them. A glance at the absorbed doses from current nuclear medicine procedures given in the cited NCRP report (NCRP 1985c, Table 1.1) attests to the effectiveness of the vigilance in both the nuclear medicine and radiation protection sectors, toward keeping the radiation doses low.

III. Effects at the Cellular Level^(a)

A. The Setting

This is a unique chapter in our field of interest. In chapter 10, we noted that many of the substances used in tracer chemistry and nuclear medicine involved the presence of radionuclides placed in the precursors of nucleic acid synthesis or other important building blocks for cellular metabolism and growth. Many of these have been used primarily in cellular radiobiology where tritium-labeled, iodine-labeled, or carbon-labeled DNA or RNA^(b) precursors have been applied extensively to unravel the basic mechanisms of cell growth and division and to identify the principal target molecules for radiation damage. In such instances, the labeling activity is limited to what is needed to provide good measurements. The site of localization can be handily determined by the application of sophisticated autoradiographic methods. The work began late in the 1950s in many laboratories of cellular radiobiology and molecular biology. It contributed much to our knowledge of the origins and development of the important cell populations from the original "stem cells." One of the earlier

(a) Obviously, the genesis of nearly all effects we have been discussing is at the level of the individual living cell. However, the results are most frequently expressed primarily in more complex integrated systems involving organs or tissues. In this section, we are concerned with events that not only begin at but are expressed primarily at the cellular level of organization.

(b) Ribonucleic acid.

examples, from Quastler and Sherman (1959) working at Brookhaven and Brown University, concerned cell population kinetics in the intestinal epithelium of the mouse. Labeling was done with either ^{32}P or ^3H ; the former as the phosphate, the latter in thymidine. Good early summaries of the usefulness of the tracer-level work are given by Hughes et al. (1958), Bond et al. (1959), and by Cronkite et al. (1962) primarily at Brookhaven. A few of the administrations were to humans.

A parallel development involved higher than tracer-level activities and was directed at the overt production of effects, especially cell "killing"^(a) under a variety of circumstances.

We wish here to examine the toxicologic overtones of the tracer uses and the toxicologic findings at the higher activity levels.

B. Uses to Establish Mechanisms

Radionuclides that could be synthesized into biologically important molecules, especially the nucleic acid and protein precursors underlying cell growth and development, were used in two major ways: (1) primarily as tracers, and (2) as carriers of radioactivity into these primary structures. The latter is a unique application of the toxicology of radionuclides, since it has been used extensively to unravel the mechanism of cell killing by radiation. Both constitute most important and scientifically useful facets of the story of the radionuclides.

The tracer level work contributed to two very different problems. First was its application to tracing the growth and differentiation of major cell lines. The origin of many cells (especially those involved in blood formation, but also germ cells, antibody-producing cells, malignant cells, and nearly all other cells that turn over rapidly) had been most difficult to work out by morphological techniques alone. The advent of labeled compounds, which would enter the cycles of growth and development and could, moreover, produce clear autoradiograms without undue radiation dose to the cell, was a major advance. Excellent vignettes of the techniques and results can be found in volume 2 of the International Atomic Energy Agency (IAEA) publication, *Tritium in the Physical and Biological Sciences*. The review by that stellar hematologist Eugene Cronkite and his colleagues from Brookhaven is especially complete (Cronkite et al. 1962). (Obviously, other synthetic processes, such as synthesis of DNA [Bianchi, Crathorn, and Shooter 1962] could be studied also.) A glimpse of the work with microorganisms can be seen in Painter, Forro, and Hughes (1958) working at Brookhaven and Yale.

The second tracer use was to mark the sites in dividing cells where radiation damage might be occurring.

While tritiated thymidine has now been used in nearly every laboratory interested in cellular radiobiology, the work started at Brookhaven National Laboratory (Taylor, Woods, and Hughes 1957),^(b) and the group there has remained

(a) Although it became customary to call the effects "cell killing" and the quantitative relationships "survival" curves, the process was really inhibition or prevention of cell division and growth, i.e., it was a reproductive death. Such cells might continue to live as "resting" cells.

(b) Also in Belgium independently by Verly and Hunebelle (1957).

active ever since.^(a) As the work progressed and the collaboration of the synthetic chemist and the molecular biologist became ever more fruitful, many other nucleic acid precursors were labeled (e.g., cytosine). The autoradiographic technique has been a powerful tool in depicting the cellular localization of these substances (Taylor 1962; Maldague, Que, and Maisin 1962; Schultze and Maurer 1962; and Woods 1962).^(b)

The use of higher activity levels to produce cell killing in specific systems began at Washington University, St. Louis, spread to Brookhaven and later throughout the scientific community interested in identifying the major targets for radiation damage. Such work was largely responsible for proving that it is the intracellular DNA that is the primary target in the radiation death of cells in reproduction (Okada 1970).^(c)

Much work with the higher activities involved an experimental technique called the "Suicide Experiment" (Okada 1970, p. 99 and pp. 121-132) or, as some prefer to call it, "cytocide." Hershey and colleagues (1951) at Washington University first developed the procedures. Cells are labeled by culturing them with a radioactive precursor of DNA or RNA. After sufficient time for the precursor to enter the growth mechanisms, the cells are cooled (frequently to -196°C). This stops all metabolic processes. However, the decay of the radioactive atoms continues, since this is a physical process and is independent of temperature. After allowing time for a calculated number of decays, and thus a desired radiation dose, to accumulate, the cells are warmed back to 37°C , and their further growth and division are followed. In addition, subsequent phenomena, such as mutations, chromosome aberrations, ability to perform certain specific synthetic processes, are measured. With suitable choice of precursors and observation by autoradiography, relatively precise information can be obtained on the site and kinds of damage produced.

The early work in this field used ^{32}P as well as tritiated nucleic acid precursors and organisms ranging from single-stranded viruses to mammalian cells. A useful summary of the earlier key experiments can be found in table 20.2, taken from Okada (1970, pp. 128-129).

(a) We saw some of the Brookhaven work in chapter 10. Other major contributors to this cell-level work, all of it in post-World-War-II years with major developments in the decades of the late 1950s and 1960s, were located at: Argonne Cancer Research Hospital; Argonne National Laboratory; Biology Division, Oak Ridge National Laboratory; Colorado State University (Ft. Collins); Columbia University; Donner Laboratory at the University of California, Berkeley; Laboratory of Radiobiology, University of California at San Francisco; M. D. Anderson Hospital, Houston; Ohio State University; Pennsylvania State University; University of Rochester; Washington University, St. Louis. In later years, these were joined by efforts ranging from major to supplemental at nearly every large institution engaged in nuclear medicine and molecular biology. There was, of course, much work abroad, particularly in England and West Germany.

(b) Taylor was at Columbia University; P. S. Woods at the University of Delaware; Maldague and colleagues at Louvain, Belgium; and Schultze and Maurer at the University of Cologne. Thus, we gain an idea of the rapid spread of these techniques and studies and their almost ubiquitous occurrence. Remember, too, that this is a mere sampling of the literature.

(c) Okada worked at Rochester for a number of years and wrote his major monograph while a staff member in radiation biology and biophysics.

TABLE 20.2. Efficiency of Killing of Organisms—"Suicide Experiments"

Classification	Organism	Radioactive Atom	Storage Conditions	Efficiency of Killing (α)	N ^{a,c}	Reference ^a

^b Not described.^c N^a is the number of radioactive atoms expressed per DNA or per organism (phage, bacteria, and cell): (a)(a) While this is verbatim from the original, obviously this column supplies no numbers. Instead, the designation given signifies the entity (DNA or organism) interacting for the quantity N^a.

Source: Reser from Okada 1970. Reprinted with permission of Academic Press, Orlando, Florida, copyright 1970.

The "efficiency of killing" (α) is derived from the classical equation relating survival (i.e., ability of a cell to divide) and radiation dose. Fortunately, most of the relations are exponential (or can be handled as exponentials). Thus:

$$S = S_0 e^{-\alpha D}$$

where S_0 = original number of living organisms

S = the fraction of organisms surviving after decay of a stated number of radioactive atoms

D = dose

α = efficiency of killing

Table 20.2 indicates the high efficiency of ^{32}P in the very simple systems. The near unity α figure for killing of a single-stranded DNA virus by ^{32}P means that decay of one radioactive atom is enough to disable the system. The needed number of disintegrations naturally increases in progression to double-stranded viruses and on to more complex systems like bacteria, yeast, and mammalian cells, which have more units requiring disabling before cell division is inhibited. Many variations occur as a function of strain of cell, heterogeneity of the cell population, stage in DNA replication, amounts of DNA per cell, etc. However, the principle has been established.

It will be noted that the efficiency of killing of mammalian cells by ^{32}P decay is considerably less than that for tritium. This could mean a greater efficiency of the very localized radiation of tritium compared to ^{32}P . Okada (1970, pp. 129-130) cites other possible reasons for the difference.

The importance of chemical factors, or at least the chemical nature of the carrier of the radioactivity, can be seen in an important paper by Burki and Okada (1968).^(a)

They found that the killing efficiency of tritium was markedly reduced when it was attached to uridine, which labels RNA rather than DNA, or when it was attached to histidine or lysine, which placed the radioactivity in the so-called acid-soluble rather than the protein fraction. By a maneuver that placed the label in the cytoplasm rather than the nucleus, they also found a decrease in efficiency. When the suicide technique was applied to other cellular effects besides reproductive death, it was also found that the nature of the precursor played an important role, and it was different from that in reproductive death. This was particularly noticeable in the induction of mutations in bacteria (*E. coli*) (Person, Snipes, and Krasin 1976).

These experiments enabled estimation of the size of genes and, perhaps most importantly, demonstration that the killing efficiencies for reproductive cell death followed the same progression as the ratios of calculated target volume divided by the DNA content of the organisms. This applied when similar calculations were made using x-rayed cells and could be used as proof that DNA is likewise the target for radiation-induced inhibition of cell division by external radiation.

(a) This work came from the Division of Experimental Radiology at the University of Rochester and the Donner Laboratory at Berkeley. Dr. Burki received his doctorate under the direction of Okada and went ahead to carve out an important career in cellular radiobiology at Berkeley. His untimely death in midcareer leaves a significant amount of work undone, as well as much good work completed.

C. On the Radiation Dose to the Cell Nucleus

Since the radiations involved in some of these experiments were of very short range, it seemed doubtful if the doses associated with the phenomena just described could be calculated correctly by the conventional system, since this used an average dose over a volume much larger than a single cell or its nucleus.

Again, the first serious approach seems to have come from Brookhaven. At the first National Biophysics Conference held in Columbus, Ohio, March 4-6, 1957, J. S. Robertson and W. L. Hughes presented a paper that developed from their recent success in localizing high-specific-activity tritium by micromapping techniques within cell nuclei.^(a) In this milestone paper, Robertson and Hughes (1959) deduced that a single disintegration of tritium delivers a dose averaging 53.5 rad to an inner sphere 0.5 μ in diameter and 5.8 rad to the next 0.5- μ shell. This is not the dose to the cell nucleus, since most cell nuclei are several microns in diameter. More than one disintegration of tritium would be needed to apply this dose to a whole nucleus. However, the potential for selective radiation of even parts of the nucleus is apparent, a powerful tool when combined with localization by autoradiography.

Obviously, if the tritium is deposited as a single point source, the dose will fall off rapidly with distance, as shown in figure 20.3, taken from the paper by Robertson and Hughes.^(b)

FIGURE 20.3. Radiation dose rates about a point source of tritium. (Redrawn from Robertson and Hughes 1959. Reprinted with permission of Yale University Press, New Haven, Connecticut, copyright 1959.)

(a) As we have already seen, this resulted in selective irradiation of cell nuclei and of the DNA, which is found only in chromosomes, with relatively low radiation dose to the cell cytoplasm.

(b) It seems likely that this work began James Robertson's life-long interest in radioisotope dosimetry. He continued at Brookhaven for many years and made important contributions there. After his move to the Mayo Clinic, where he was a consultant in nuclear medicine, he had much influence on the MIRD developments, as we have already seen. He has also chaired or participated on many national committees with dosimetric charters or overtones. For example, he currently chairs the NCRP scientific committee charged with the experimental verification of internal dose calculations (NCRP 1985c). Still more recently, he joined the Headquarters staff of DOE and chaired the MIRD Committee in 1985.

This work ties in with the general problems of discrete radioisotope sources that we saw as the "hot particle problem" in chapter 9. It also relates to, but is on a different scale from, true microdosimetry as espoused by Harold Rossi and his colleagues at Columbia University, and many others (see, for example, Rossi 1967, whose work is at a still more micro level).

Robertson and Hughes were joined by Bond, Johnson, and Cronkite, among others, from Brookhaven and by Ludwig E. Feinendegen, who was headquartered at the Institute for Medicine in Jülich, West Germany, but who spent considerable time with the Brookhaven group to expand cellular-level dosimetry and to do experiments bearing on the effectiveness of the doses delivered by the various pertinent radioisotopes.

A paper by Bond and Feinendegen (1966) was a second milestone on the subject from Brookhaven. It used as a model bone marrow cells from a rat that had received $1 \mu\text{Ci}$ of ^3H - TdR per gram of body weight. They determined radioactivity levels radiochemically and autoradiographically. Using the average nuclear diameter as 8μ and the corresponding mass as 270 pg ,^(a) they calculated an average dose rate of about 8 rad per day to the nucleus. (Note that this is the average dose from tritium given at the level of $1 \mu\text{Ci}$ per gram of body weight and thus involves more averaging than the point source calculation of Robertson and Hughes.)

A third milestone paper from Brookhaven on the subject of dose to the cell nucleus came from Johnson in work described at the 1969 Oak Ridge symposium on medical radionuclides (Johnson 1970). By this time, the possible extra effectiveness of sources such as the tritium beta particle within cell structures was causing much consternation among those charged with radiation protection. Did we have a Trojan horse in our midst? Extrapolations were made by some, quite unreasonably, from the situation where the radioactivity was entering already incorporated in important biomolecules to situations such as the entry of tritiated water, even tritium gas, which we looked at in chapter 10. It was forgotten that only a small fraction of the radioactivity entering in these ways reaches dividing cells. The Johnson paper clarifies much of this.

Johnson adopted a two-pronged approach, calculation of dose and direct experimental comparison of the effects of a given calculated dose from tritium with the same dose from external high-energy radiation.

For the calculation, Johnson accepts the basic figures derived earlier but hastens to point out some of the complications. For estimation of nuclear dose associated with the biological effects produced, Johnson reviewed experimental work on mutation, chromosome aberrations, cell killing both *in vitro* and *in vivo*, tumor induction, and animal mortality. Although many of the dose estimates are quite approximate, the general conclusion could be drawn that the yields of effects from intracellular tritium were reasonably near to those expected from the dosage calculations. Thus, for the killing of mammalian cells *in vivo*, it appeared that calculation of absorbed dose to the nucleus from ^3H - TdR on the basis of energy absorbed per mass of nucleus gave a reasonable picture of expected effectiveness. In other words, no special factor needed to be introduced, even though the energy was absorbed almost entirely within the target molecule. (This does not mean equal effectiveness of an average whole-body dose for external radiation compared to ^3H - TdR, only comparability of

(a) This is now defined as the "reference nucleus."

absorbed doses in the quite radiosensitive structures we are dealing with. Effectiveness of a given dose in the nucleus may be well above that of the same dose averaged over the body. Indeed, the average dose to tissue is probably meaningless for substances incorporated into the cell nucleus.)

This paper led Allen Brodsky, who was then at the University of Pittsburgh, to deliver a eulogy on the virtues of tritium, as part of the discussion following Johnson's paper (1970). It is reproduced below.

BRODSKY: "Bravo" to Dr. Johnson's paper on tritiated thymidine. I have felt for some 9 to 10 years, since investigating the problems of tritium released to the environment, that tritiated thymidine was no more than about 100 times more radiotoxic than HTO. Even a factor of 100 increase in relative radiotoxicity per microcurie, based on a calculated dose rate to the genetic material, would still not put tritiated thymidine very high on the relative radiotoxicity scale. The relative ease with which tritium may escape into the environment has often been cited to indicate that tritium is a "hazardous" nuclide. However, in many research laboratories not enough tritium is handled at any one time to constitute a real hazard even in thymidine form. Furthermore, in estimating the hazards of tritium dispersed to the environment, he concluded that the probability of genetic mutation from ^3H transmutation to ^3He (assuming every transmutation deleterious) was even lower than the probability of radiation genetic mutation produced by the average beta dose to tissue fluid. This seems to agree with experimental results. So I would like to raise the flag again and say, 'Hail tritium.' It is God-given to us as the safest nuclide to use for these purposes.

(Brodsky 1970)

This statement cannot help but indicate how the worry that the possibility of a "special effect" had become imbedded in the biomedical community. It is of special interest since it came from one who is not prone to unbridled fits of enthusiasm.^(a)

Before leaving the subject of dose calculation to the cell nucleus, we should examine a useful summary table assembled from many sources by a committee of the NCRP chaired by Eugene P. Cronkite at Brookhaven. Taking a reference nucleus as defined earlier and the radiation distribution as either random *in the tissue as a whole* or random *within the reference nucleus*, factors were arrived at to convert disintegrations of a given radionuclide to absorbed dose in rad. They are shown in table 20.3, taken from the NCRP report (NCRP 1979).^(b)

The difference between a "within the nucleus distribution" and a "within the tissue distribution" is frequently quite large. Only with tritium (table 20.3) is the difference only on the order of 20%. Obviously, the higher the energy and the greater the range of the beta particles, the greater will be the dose to the nucleus from *outside* and the lesser the dose from *inside* if there is generalized distribution. Even tritium, however, loses a little energy from the nucleus by the "edge effect." Iodine-125 is a special case, which has the highest average

(a) As we shall see shortly, Brodsky's factor of one hundred may even be too high.

(b) Other members of this committee and their host institutions at the time are: Edward Alpen, Donner Laboratory; Michael Bender, Brookhaven; James Cleaver, University of California, San Francisco; Ludwig Feinendegen, Jülich, West Germany; Marylou Ingram, University of Miami; H. A. Johnson, Tulane (formerly Brookhaven); Frank Lowman, Environmental Research Laboratory of the Environmental Protection Agency; Eugene Oakberg, Oak Ridge National Laboratory; Stanley Person, Pennsylvania State University; and Edward Powers, University of Texas, Austin.

absorbed dose in the nucleus, even though it is more energetic than tritium. This is because the energy appears as Auger electrons. (More about ¹²⁵I in a following section.)

D. Effects and Relative Effectiveness

The crescendo of work on biological effects and the relative effectiveness of different radionuclides and of different vehicles for bringing the radioactivity into the cell can only be hinted at in the space at our disposal. Much of it is at the heart of cellular radiobiology and has been fully reviewed by others. Yet, a few key findings and the trends of the work require attention. We will organize the review on a more or less chronological basis.

Obviously, the "suicide experiments" were effects studies, and many go back as early as 1959 (table 20.2). However, these were so focused on mechanisms that we preferred to discuss them as a separate entity rather than in this section concerning general effects.

Among the early general effects studies was work by the Brookhaven group on mouse spermatogonia. Johnson and Cronkite (1959) chose mouse spermatogonia as an early indicator of the effectiveness of intranuclear tritium because of their demonstrated great radiosensitivity (LD₅₀ of only 20 to 25 r of ⁶⁰Co 1.25-MeV gamma radiation). They chose doses of 0.5, 1, 5, 10, and 20 μ Ci/g body weight of tritiated thymidine and gave them intraperitoneally. On the whole, the effectiveness was low. Doses under 1 μ Ci/g (a sort of dividing line above which effects might be expected) were equivalent to less than 2 r of gamma radiation per day. A later report (Johnson and Cronkite 1967) continued to show low effectiveness at 5 as well as 1 μ Ci/g body weight.

There was also much work at Brookhaven on plant material such as root systems in *Zea Mays*, on *Tradescantia* (the liverwort), on the blue-green alga

Chlorella, and others. A good summary of the Brookhaven and other work was made available fairly early by Wimber (1964), who soon after went from Brookhaven to the University of Oregon. Wimber emphasizes the need for further extension of the studies, even though at that early date he could present a summary table with forty-five entries and organisms ranging from bacteriophage and bacteria through simple plants and plant root systems to rats, mice, and human cells in tissue culture. (Since the reference is readily available, the table will not be reproduced here.) The effects were inhibition of root growth and of cell growth, chromosome breakage and aberrations, various morphological changes in cells, tumor induction, and mutations.

Brooks et al. (1976) in collaborative work from Brookhaven and the Lovelace Foundation Inhalation Toxicology Research Institute studied the effects of continuous intake of tritiated water on liver chromosomes in mice. The experiment ran out to seven hundred days. They used the standard technique of a partial hepatectomy to stimulate liver cell division and maintained the animals at a level of $3 \mu\text{Ci}/\text{ml}$ in the drinking water. There was a higher level of chromosome damage in the treated animals, but it was difficult to establish statistical significance. It appeared that the effectiveness of the tritium beta particle was comparable to other beta-gamma emitters on a per-rad basis.

The group at ANL reported the induction of tumors in mice by radioactive thymidine, first in rather preliminary reports in 1961 and 1962 and then in 1966 in a definitive study (Baserga, Lisco, and Kisielewski 1966). This work was the first to demonstrate tumor production by tritiated thymidine. They gave tritiated thymidine to embryonic, newborn, two-month, six-month, and twelve- to fourteen-month-old mice in doses ranging from 0.1 to $10 \mu\text{Ci}/\text{g}$ body weight. They also administered thymidine labeled with ^{14}C rather than ^3H .

First, there was a marked difference in effectiveness between ^{14}C - and ^3H -labeled thymidine. No increase in tumor incidence was seen with the ^{14}C (in newborn at levels from 0.02 to $2.0 \mu\text{Ci}/\text{g}$ body weight), except for a statistically significant increase of lymphomas at the highest dose. By contrast, the ^3H -thymidine increased the incidence of rare tumors and accelerated the incidence and increased the total number of tumors of more frequently observed varieties. In considering mechanisms, the authors note that, while the biological half-life of tritiated water is only twenty-four to thirty-six hours, the tritium incorporated into DNA remains until the death of the cell or its dependents. However, only 10% of injected thymidine gets incorporated into DNA, and the amount present decreases with time as labeled cells divide and some are eliminated from the body. This bespeaks some form of multiplicative mechanism in the carcinogenesis, although the long retention of the radioisotope and relatively high initial dose may be sufficient in themselves.

The lack of effectiveness of ^{14}C -labeled thymidine is readily explained by the dosimetry. With the average range of the ^{14}C beta particle in tissue at about 10μ , much of the energy is dissipated outside of the cell nucleus.

At about the same time, the Brookhaven group compared the leukemogenic effect of ^{60}Co 1.25-MeV gamma radiation with ^3H -thymidine and ^3H -cytidine using mice. A preliminary report appeared in 1963. Only the mice receiving ^{60}Co gamma irradiation developed thymic lymphomas. Even by 1967 things did not change very much, despite a much larger experiment. The mean life spans and age-specific mortality rates in animals receiving 1 to $5 \mu\text{Ci}/\text{g}$ of tritiated thymidine or 400 R of gamma radiation were indistinguishable from those of control animals (Johnson and Cronkite 1967).

Meanwhile, at the M. D. Anderson Hospital in Houston, Dewey and colleagues compared tritiated thymidine, tritiated water (HTO), and ^{60}Co gamma rays for effectiveness in producing chromosome aberrations in cultured cells from the Chinese hamster (Dewey, Humphrey, and Jones 1965). The irradiation times in this in-vitro system were from ten to twenty-three hours. If any special effect of the radiation borne in by the nucleic acid precursor exists, it should turn up in a comparison of this sort. Instead, the energy absorbed in nucleus or chromosome from the ^3H - TdR beta particle was *less* effective than that from HTO or the gamma rays from ^{60}Co . The doses to the nucleus needed to produce two visible aberrations were calculated as 820 rad, 490 rad, and 520 rad for ^3H - TdR, HTO, and ^{60}Co , respectively.

Not all of the work was with cell cultures or cells extracted from treated animals. Some conventional carcinogenesis work was done in the late 1960s at the Argonne Cancer Research Hospital^(a) and Department of Radiology of the University of Chicago. Mewissen and Rust (1973), for example, reported at the Las Vegas tritium symposium on work involving over fourteen hundred newborn C57 Black/6 mice that were injected with 0.3 to 1.5 $\mu\text{Ci/g}$ body weight of tritiated thymidine with "cold" thymidine as a control. Four tumor types were studied in detail: lymphosarcoma, reticulum-cell sarcoma, hepatoma, and miscellaneous other tumors, mostly fibrosarcoma. In contrast to some of the work quoted earlier, there was a significant increase in overall tumor incidence, especially of lymphosarcoma. The total exceeded 70%, but the results indicated that the effect was more a triggering than de novo induction of the tumors.^(b)

The group at Ohio State had much interest in iodine and iodinated nucleic acid precursors. They compared intranuclear ^{131}I with ^{125}I and ^3H using a strain of leukemia cells in tissue culture. The iodine isotopes were given as iodo-deoxyuridine compounds and the tritium as ^3H -thymidine. In this work, the ^{131}I and ^3H gave almost identical results, despite their very different energies. By contrast, the ^{125}I was four to five times more toxic, and the survival curve looked like the ones typical of high-linear-energy transfer (LET) radiations such as neutrons and alpha particles. The curves for ^{131}I and ^3H were like those typical of low-LET radiations.^(c)

(a) Supported largely by AEC. The work also had support from IAEA, the National Institutes of Health (NIH), and Euratom in Brussels. A useful summary of the organization and work of the Argonne Cancer Hospital was supplied to the author by L. H. Lanzl. It is regretted that space has not allowed expansion upon the important contributions of this group. Many of the names have been met in earlier chapters since collaboration with ANL was close. Interested readers wishing more detail should contact the author.

(b) The policy in this book (see preface) is to concentrate primarily on reporting work done and the author's interpretation of the data, all in historical context. Critical evaluations based on subsequent work are not our primary objective, although there are some. However, it is necessary here to mention that the C57 Black mouse has such a high incidence of spontaneous tumors that complex statistical analyses are usually needed to establish an effect, and it is still more difficult to establish causation. This work should probably be repeated with one of the newer strains of mice with essentially zero incidence of many pertinent tumor types. This is especially important since there are those who believe that neither tritium nor ^{14}C is carcinogenic (Cronkite 1982).

(c) See discussion of relative biological effectiveness in chapter 10.

This contrast is shown in figure 20.4, taken from the paper by Hofer and Hughes (1971).^(a)

FIGURE 20.4. Fraction of L1210 cells surviving various radioisotope doses, plotted as a function of disintegrations per cell per hour. (Redrawn from Hofer and Hughes 1971. Reprinted with permission of Academic Press, Orlando, Florida, copyright 1971.)

This relationship shows that if there is to be anything "special" it is more likely to be resident in ^{125}I than in tritium or ^{131}I .

We have already reviewed the effects studies with tritiated water and tritium gas in chapter 10. There we concluded that, while tritium was hardly innocuous, it could be set down as a relatively benign radionuclide. Now we can say that, despite early fears of very severe damage to cells when the tritium (or other radionuclide) is placed within the cell nucleus, the effectiveness overall is not increased by so large a factor as was anticipated. Part of this is because relatively small amounts of the label actually reach the final goal. We shall examine implications of these phenomena for radiation protection in humans in section F.

E: The Transmutation Problem

In chapter 10, section IV D, we briefly mentioned the possible existence of a transmutation problem when radionuclides disintegrate within cells. We indicated that if our respective patience held out we would discuss it in connection with the toxicologic aspects of tracer chemistry and nuclear medicine. The writer's patience has held out and he hopes the reader's patience has been

(a) This is about as far into cellular radiobiology as we can go in a book devoted to the toxicology of radioactive materials. Readers interested in delving more into the derivation and usefulness of the survival curve can find a lucid explanation in the monograph by Okada already cited, and in the *Textbook of Radiation Biology* by A. P. Casarett (1968, especially chapter 7) or, if they desire to go back to the original derivations and concepts, in the classic book by D. E. Lea (1955).

similarly durable. It is a problem we cannot fail to mention, even though it has turned out to be largely a "red herring" for practical radiation toxicology. If we did not discuss it, someone would dredge it up *de novo*.

The "Transmutation Problem" refers, of course, to the fact that in many radioisotope decays the product is a different element from the original.^(a) Theoretically, a possible transmutation effect might be resident in every situation we have discussed. However, relatively few of the radionuclides we have dealt with become incorporated in biologically critical molecules, and hence the transmutation to a new element is a trivial matter. Furthermore, even at high concentrations of radionuclides, the number of atoms undergoing transformation is a tiny fraction of the atoms in cells and tissues. However, there is not so much redundancy in the cell nucleus or in critical molecules such as DNA or RNA. Also, the elements of primary interest, phosphorus, tritium, carbon, and iodine are easily incorporated into the basic structure of the nucleic acids, and it is conceivable that transformation of phosphorus to sulfur, tritium to helium, or carbon to nitrogen, for example, in the backbone of the cell's growth and hereditary mechanism might be damaging in a special way. This includes sometimes a transfer of electrical charge.

The only way to attack this problem experimentally is to do careful dose-response work and see if the effects can be accounted for on the basis of the radiation dose, or if they markedly exceed those expected from the calculated dose. (It would have to be a fairly substantial effect because of the inaccuracies of the dose calculation.) All of the work has involved cellular-level systems.

Radiophosphorus. Early work concerned the transformation of phosphorus to sulfur. The ^{32}P beta particle is of such high energy that even when incorporated into DNA much of the energy is dissipated outside of the nucleus. Hershey et al. (1951) at Washington University in St. Louis and Stent and Fuerst (1955) at Berkeley showed clearly that lethality in bacteriophages resulted from transmutation when ^{32}P was incorporated. Also, it appeared, as we saw in table 20.2, that every decay produced a break in the single-stranded DNA of such a simple system. As reviewed by Krisch and Zelle (1969)^(b) and in the NCRP report already cited (NCRP 1979), evidence of a small transmutation effect in *Drosophila* also appeared. In mammalian systems, it was clear that the process had a very low efficiency.

Tritium. Much more work has been done with tritium than any other incorporated radionuclide, largely because the transformation from hydrogen to

(a) Sometimes the term includes all of the phenomena except the release of ionizing radiation. In addition to chemical change due to the atomic number change, there is the possibility of production of an excited chemical state, nuclear recoil effects, etc., all at a very local level. There is no strict tradition in radiation biophysics as to which definition to use for transmutation, the total of the local effects or only the effects of chemical change due to change in atomic number. For the weak beta emitters of primary interest to us here, recoil and excitation effects are expected to be very minor, with the possible exception of ^{32}P . An excellent discussion appropriate for the biomedical scientist of the local effects and those along the path of the beta particle is given in the review of transmutation effects by Krisch and Zelle (1969), written while Zelle was Director of the Biology Division at ANL.

(b) This review is among the most complete and readable descriptions of the phenomena and experimental work to the date of its writing.

helium would almost certainly break the important carbon-hydrogen bond, thus changing the molecule chemically. It can also result in a positively charged carbonium ion. Much of the interest began and has persisted at Brookhaven, at Berkeley, and at Penn State.

A review of experiments with mammalian cells by Bond and Feinendegen (1966) led to the conclusion that somatic effects could all be accounted for by calculated average radiation dose down to 5 rad or less; this means down to a mass of 10^{-11} g or less. They further concluded that the tritium atoms are randomly distributed into the DNA and that every part of the cell lies within range of at least one tritium beta particle. The work was reevaluated by Feinendegen and Bond (1973). While the story for mammalian cells held up, some exceptions had begun to appear. These were further evaluated by Carsten (1979) as part of his important sequence of investigations on environmental tritium (chapters 10 and 13).

A transmutation effect from incorporated tritium was demonstrated in microorganisms such as the bacterium, *E. coli*. Varying the position of the tritium atom in the protein precursors was the key. In general, all effects could be accounted for entirely on the basis of the beta-particle dose, with the exception of three cases involving mutagenesis. When the tritium was given in uridine or uracil^(a) rather than thymidine and placed in the number 5 carbon of the ring, it was seven times as effective in producing mutations as decays from tritium in the number 6 ring carbon. A mechanism was suggested by Person, Snipes, and Krasin (1976) working at Penn State. They also showed that tritium located in the 6 position of the thymidine ring or the 2 position of the purine, adenine, produced significantly more effect than in other positions or expected from the beta dose. Thus, under special circumstances, a real transmutation effect can be demonstrated in bacterial systems.^(b)

Work with the fruit fly, *Drosophila*, done at Leiden in the Netherlands by Kieft (1968) indicated a somewhat similar situation. Again the 5 position in uridine appeared to be the most effective. The extra effectiveness was a factor of two to three rather than the factor of seven seen in *E. coli*. Again also the phenomenon was limited to mutations, or appeared to be. Some work on carcinogenesis in *Drosophila* by Ghelelovitch (1969) indicated a reverse situation with tritium in the 6 position being more effective. Unfortunately, the *Drosophila* work did not have the benefit of measurements of tritium incorporation in the cells and tissues, and we thus have no dosage calculations. The evidence is limited to the similarity of the position effect to that seen in bacteria.

Meanwhile, work with mammalian cells continued to show no measurable transmutation effect. Lambert, at the Radiological Protection Service in the United Kingdom, measured cytological damage in mouse testes. He could find no difference between either x rays delivered at an exponentially decreasing dose rate to imitate the kinetics of a dose from tritium (compare chapters 8 and 10)

(a) Uridine, uracil: nucleic acid or protein precursors.

(b) This conclusion is not accepted for lethality or other processes, only for mutations. Even for them there are those who postulate that the special effectiveness could as well be a "more efficient irradiation" of the DNA by a positional effect in the molecule. Such positional effects have been shown in inactivation of bacteriophage (Feinendegen and Bond 1973).

and beta doses delivered from either tritiated thymidine or tritiated water in producing cell death over a seventy-two-hour period (Lambert 1969).^(a)

Cleaver, Thomas, and Burki (1972), at the University of California, San Francisco and Berkeley, did a suicide-type experiment with Chinese hamster cells and measured DNA strand breaks. Although the dose-effect curves had different slopes, they concluded that the damage resulting in this system from decays of ^3H -TdR in DNA is no greater than that predicted from the beta-particle irradiation.

Each of the studies cites work of others with similar outcomes. Feinendegen and Bond (1973) completed their re-examination of the old evidence and the new evidence to 1973 with the conclusion that no modification of the earlier statements was needed, i.e., that transmutation is not a significant factor in the effectiveness of tritium decaying in the nucleus of mammalian cells. No one since has found reason to modify this view. However, it is also generally accepted that certain bacterial cells (perhaps all prokaryotic cells)^(b) and mutations in *Drosophila* are different from mammalian cells mechanistically.

Other Radionuclide Labels. What can be said about transmutation by the other low-energy, short-range radionuclides that, like tritium and phosphorus, can be incorporated into the biologically important precursors of cell growth and division? The best sources of information on these are NCRP Report 63 (NCRP 1979), especially Section 3.4 and Appendix VII and, the review by Kršich and Zelle (1969).

When ^{14}C decays, the result is a nitrogen atom, a situation that can break important molecular bonds and possibly contribute to cell damage. Such work with ^{14}C is very difficult. Because of its long half-life, undesirably high specific activities are needed. Also, its energy, while low by most standards, is high enough that a larger proportion of its deposition may be outside of the labeled nucleus. Nevertheless, some information on chromosomal aberrations and mutations suggests a transmutation effect in material such as onion root tips and bean plants and *E. coli* and possibly in *Drosophila*. Again, it is only when the label is in a specific position, this time the 2 position in thymidine, that the effect is noted. However, there have also been many completely negative experiments. On balance, the effect would appear to be negligible. If any extra effectiveness applies only to one position, labeling of that position would normally be quite infrequent and the effect thus lost in the "noise" of other events.

Sulfur-35 decays to ^{35}Cl , and this might produce transmutations if there were much sulfur label in the nucleic acids. However, it appears that ^{35}S does not get incorporated into DNA. It is not surprising, therefore, that work at Reed College by Hungate and Mannell (1952) using the fungus *Neurospora* was negative.

(a) The initial results indicated that the ^3H -TdR was about four times as effective as HTO on the basis of injected dose. However, dose calculations showed that the 20 μCi of HTO gave a dose of 12.2 rad to the testes and therefore to the cell nucleus, and the 5 μCi of ^3H -TdR/g body weight delivered about 14.7 rad to the nucleus. The external dose from the x rays, for equivalent effect, was about 30 rad. Lambert considered the problems of dosimetry sufficiently complex to regard these results as in essential agreement, although he did suggest an RBE for tritium greater than unity as we saw earlier.

(b) Cells with their nuclear material scattered in the cytoplasm rather than gathered in an organized nucleus.

The story with iodine isotopes is essentially negative, despite many attempts to find transmutations from the widely used iodinated compounds. Only in the special case of ^{125}I with its Auger electron effect is there a special effectiveness. And this is not a transmutation effect at all. (a)

It should be stressed here that, even though there does not appear to be a transmutation effect of significance for mammals, the work was eminently worth supporting. First, we would still have the nagging worry over a possible transmutation effect in potential exposures of humans unless the host of workers (only some of whom we have cited) made these careful studies. Second, the development of ideas about mechanisms of mutation was materially advanced and so was cellular biology by the application of this unique extension of radioisotope toxicology. The support of government for such work has been of the greatest importance.

F. Implications For Man

It is customary among those working in nuclear medicine and tracer chemistry to state that exposure of man to the labeled precursors of cell growth and division that we have been discussing in this section is trivial. In comparison to the millions of exposures to other compounds occurring in nuclear medicine, this is indeed true. Also, the handling of the tritiated, iodinated, and other labeled moieties in tracer chemistry is usually done in large institutions with well-organized radiation protection services. Nevertheless, the subject of possible exposure of humans cannot be, nor has it been, dismissed. Let us review the evidence gathered in part.

We can relax about transmutation. Only under very highly specialized laboratory conditions requiring special efforts to incorporate the radionuclide into a specific position in a specific molecule can this effect be important. Even this seems not to apply to mammalian cells. For ordinary environmental or laboratory exposure, a very small percentage of incorporations go into the specific molecule of interest and only a small percentage of these go to the critical position. Only after long-term chronic exposure would there be measurable incorporation in vivo.

What of planned administrations to patients? The importance of the labeled compounds as tracers for the development of cell lineages and for determination of cell growth rates and mechanisms inevitably led to a few instances where the animal data simply would not suffice. The process had to be studied in humans to depict their unique cell production and lineage processes. Tracer-level doses have been given to selected patients. Examples are:

1. Labeling indices of normal and malignant cell populations that have occasionally been studied in vivo, largely by the Brookhaven group. See, for

(a) The Auger effect is described well for biomedical scientists by Krisch and Zelle (1969). Electron capture is the first event, which results in a vacancy in the inner shell of the atom, which is filled by an electron from the outer shell. Considerable energy is released locally in this process, and it may cause the ejection of another electron with a repetition of the whole process. Thus, the effect described by Auger has been called a vacancy cascade. It can produce intense but very localized energy releases. Rosalyn Yalow refers to the vacancy cascade as "catastrophic" decay (as mentioned by Myers 1984).

example, Cronkite et al. (1962), especially table IV, p. 201 and citations therein. Incidentally, the labeling index was lower than for rapidly growing cells of the blood-forming system.

2. Work by the Brookhaven group with a brain tumor patient who was terminal and comatose (Johnson et al. 1960). Injections of ^3H -TdR were given at times calculated to be close to the end of the patient's life, and the labeling of the neoplastic cells in the brain tumor was studied post-mortem by autoradiography. It appeared here, also, that the cancer cells were dividing more slowly than nonneoplastic cell populations.
3. A series of studies by Martin Lipkin and associates at Cornell University Medical College and Sloan-Kettering Institute for Cancer Research in New York utilized tritiated thymidine to measure generation times and phases of the proliferation cycle in cells of the human intestinal tract. This was very complete work. A pair of papers in 1963 described work on patients requiring surgery of the colon and rectum (Lipkin, Bell, and Sherlock 1963) and of stomach and ilium in addition (Lipkin, Sherlock, and Bell 1963). The doses of tritiated thymidine were very low (0.02 to 0.26 $\mu\text{Ci/g}$) and would thus be of no significance from a radiation protection standpoint. Most of the later work utilized animals or in-vivo techniques, but Lipkin has established the cell sequences and turnover times throughout the human gastrointestinal tract. All of this was by use of tritiated nucleic acid precursors.
4. In addition, work was done at Western Reserve University on the cell renewal processes in human rectal mucosa (Cole and McKalen 1961, 1963), which further documents uses of these labeled compounds in man. Here 10 mCi of tritiated thymidine were given to patients shortly before surgical removal of a section of the colon. In one case, biopsy material was obtained at 27 to 291 hr after surgery and the rates of cell renewal measured. In another, the growth of adenomas was measured. Somewhat similar work was done in laboratories outside of the United States.

Obviously, these are not the only such studies. There have been many others, although it must be said that most of them were concentrated in the era of the late 1950s and early 1960s. It is obvious that such procedures have been rare. Most of the labeling of human cells has been done in vitro.

Other areas of planned administrations that might involve nuclear labeling or at least specific irradiation of growing cells occurred in attempts at therapy, e.g., the use of ^{32}P in the early days of possible leukemia therapy; also the ubiquitous iodine compounds, and the occasional special compound such as a tritium-labeled drug tried for the treatment of cancer (Marrian et al. 1962).

The uses of these compounds in tracer chemistry cannot be dismissed as of no potential hazard to humans. While the chances for ingestion or inhalation are small in comparison to releases of these same radionuclides from nuclear installations or weapons, the total amounts used in major research institutions are very large. Nearly every major biomedical research installation uses from one to many of these substances. There are opportunities for release during synthetic chemistry and waste disposal procedures. Most radiation safety officers worry about their control and try to keep a close rein on their handling (Baily 1982).

That implications for humans are worthy of careful thought is amply confirmed by the fact that the NCRP convened the committee that wrote Report No. 63 (NCRP 1979) not only to review the science but to make

recommendations regarding permissible exposure levels. The Council found it necessary and advisable in some cases to recommend figures that differ from "normal" intakes of the same radionuclides. For example, a single intravenous injection of tritiated thymidine was considered about 4.3 times as effective as tritiated water and a single ingestion dose 8.6 times more effective than tritiated water. For continuous intake, a further factor was added. The same limits were suggested for other tritiated precursors, even though they incorporated less efficiently than thymidine. This is because of evidence that some of the substances are radiosensitizers. The report also suggested that the same limits be applied to RNA precursors as to tritiated thymidine.

By contrast, tritium-labeled amino acids and nonspecific precursors are not considered different, and the usual criteria for calculating dose in *tissue* rather than in cells should apply to these in the opinion of the NCRP committee.

For ^{14}C labeled compounds, the calculations showed that a bit of relaxation of allowable amounts would be in order, viz., 1.47 times as much ^{14}C -thymidine could be allowed as ^3H -thymidine, with an upper limit of 2 mCi to adult man. There was a tightening of restrictions for ^{14}C RNA precursors compared to ^3H RNA precursors, by a factor of eight in intake.

With ^{32}P and ^{35}S , it was concluded that no special consideration need be given to decays in the cell nucleus because of the relatively high energy and long range of the beta particles from these elements. Here, the ordinary concept and calculation using average dose to the organ was considered to apply.

With iodine, the precursor is 5 - iodo - 2 - deoxyuridine (IUdR), which is incorporated into DNA much as is thymidine. This iodine is labile, however, and soon enters the inorganic pool. Thus, for all isotopes but ^{125}I , the ordinary procedures are recommended. Through a series of calculations involving the Auger effects, or comparable processes (which showed a factor of twenty-five-fold higher toxicity for ^{125}I compared to ^3H and an efficiency of incorporation of $^{125}\text{IUdR}$ versus ^3H thymidine of one sixth) it is concluded that intakes of $^{125}\text{IUdR}$ should be about one-quarter those of ^3H -thymidine. (The actual intake limits vary with the route of entry, of course.)

The new ICRP publication on radioisotope standards for occupational exposure (ICRP 1979, 1982) sets aside a special category only for organic compounds containing ^3H and ^{14}C . Otherwise the broad limits on annual intake do not specify the nature of the compound, and by implication negate there being a need for separate consideration of situations when the cell nucleus is irradiated specifically. Perhaps these will be added when the ICRP addresses population exposures.

From the NCRP work, we see that the compounds of tritium, ^{14}C , and ^{125}I require special restrictions. Since these are among the most likely to be encountered, the restriction is of some practical importance.^(a) We should remember, however, that these restrictions are applied to radionuclides that have some of the highest permissible intake levels extant. Furthermore, the factor between organic compounds within cell nuclei and ordinary compounds is seen to be considerably less than the factor of one hundred that led Allan Brodsky to his great enthusiasm for tritium (see p. 1742). In the overall picture of radioisotope

(a) The people of the U.K. Radiological Protection Service made it even more practical by going to recommended maximum annual intakes for a variety of compounds of tritium and ^{14}C . The values for ^{14}C -labeled compounds are in general lower (Vennart 1969).

toxicology, these special substances are still relatively innocuous in comparison, let us say, to plutonium. Yet, they have potentials that mean that vigilance must be maintained.

These conclusions were gained only after large amounts of hard work in a number of laboratories and bespeak again the importance of support for the work.

IV. Specifics

In this section, we will take up some areas of work that have different implications from either dosimetry or cellular-level effects, which were reviewed in sections II and III. They are mostly specific to our intention of considering work related primarily to the radioisotope toxicology programs that have been the focus of interest in this book. Much has obvious toxicologic overtones. Some is taken up primarily because it represents work done in the same laboratories and by some of the same people supported by the radioisotope toxicology venture. Obviously, there is no intention of entering a comprehensive review of either tracer chemistry or nuclear medicine. Ample reference has already been made to reviews of these.

The work we will consider falls rather easily into distinct periods. The first concerns the resurgence of activity that began at the end of World War II and developments over the next decade and a half. It was a mixture of developing diagnostic and therapeutic uses of radionuclides. Because the initial emphasis was on therapy, I am calling this first period "The Era of Therapeutic Intent." It runs from about 1948 to about 1965. The second era, which began in roughly the mid 1960s and continues today, has concentrated on improvements in diagnostic procedures and is being called "The Era of Ever More Scanning and Ever Shorter Half-Life Radionuclides." A third era with a resurgence of therapeutic intent may develop out of very recent work.

Toxicologic and mechanistic considerations had important influences on each era, but they were quite different.

A. The Earlier Years—The Era of Therapeutic Intent

We have already mentioned that uses of radionuclides for therapy of disease states played a prominent role in the thinking of the pioneers in what was to become nuclear medicine. We have also seen a few examples. In the succeeding sections we will review some others.

1. Atoms for Peace

Officially the "Atoms for Peace" program was launched during the Eisenhower administration (good years for American science)^(a) with the first of the two

(a) This remark should not be interpreted to mean we know they would have been any different had Adlai Stevenson been in the White House. Conditions were very favorable for major advances in scientific research of all kinds.

Atoms for Peace conferences held in Geneva, Switzerland, in 1955.^(a) At these, the international community took the wraps off its developments in nuclear energy. However, in terms of availability of radionuclides for medical uses and for research in the United States, the bonanza had already started. Indeed, the Oak Ridge reactor (Clinton Laboratories at the time) had more radioisotopes than it knew what to do with, even before the end of World War II. Many were separated, purified, and sent to Berkeley, from which they were distributed. They were made part of the program of distribution of accelerator-produced isotopes that Berkeley already had under way. The recipients were not aware that in some instances they were receiving radioisotopes produced in a nuclear reactor. It was not yet time to break security and announce the real source.

Overt distribution of reactor-produced isotopes outside the Manhattan Project began on August 2, 1946. In January 1947, direction of the program was transferred to the newly formed AEC. Dr. Paul Aebersold, originally at Berkeley, but later at the Oak Ridge reactor, was put in charge of the Isotopes Branch of the AEC and did a superb job of meeting the needs of both science and medical practice. During the first year, over eleven hundred shipments of reactor-produced radioisotopes were made to 160 organizations and institutions. Aebersold tells the story in a paper (Aebersold 1948) given at one of the first postwar symposia held on the use of isotopes in biology and medicine. An excerpt from the conclusion of Aebersold's paper not only gives more detail but a feel for the enthusiasm for the program felt by all concerned.

The present situation respecting the availability of isotopes is indeed a happy one. Almost every useful isotope which is found in nature or producible by man is now available for the investigator, and the few that are not yet generally available can be expected to become so. Advances in biology and medicine through the use of isotopes will henceforth be limited only by the availability of personnel and facilities and by the imagination of the investigators.

This favorable situation has been the result of the interest, effort, and cooperation of a number of organizations and hundreds of persons both within and outside the Commission's program. Many sacrifices have been made in individual programs to promote the availability of isotopes. It would be impossible here to give due credit to all those who have contributed. Recognition for radioisotope distribution must be given particularly to the cooperative activities of the Chemical, Technical, and Production Divisions, and the Health-Physics Department and management of the Clinton Laboratories, which is operated for the government by the Monsanto Chemical Company.

(a) Admiral Lewis L. Strauss was chairman of the AEC at this time. He had President Eisenhower's ear, and while it is difficult to trace details, it appears likely that Strauss helped to include some of the biomedical facets of the program. Admiral Strauss's autobiography contains a moving section describing Eisenhower's speech to the United Nations on the Atoms for Peace program and the ovation it generated (Strauss 1962). His first sentences from the chapter entitled "The Peaceable Atom. . ." are worthy of note in their own right, "Providence has a way of redeeming man from his follies and even from his sins. Since time immemorial, man's inventiveness has been stimulated to produce weapons and engines for use against his enemies, most of which were eventually turned upon the inventors themselves. But finally these devices often were transmuted into peaceful tools." (Strauss 1962, p. 330)

Groups in other Commission laboratories, notably the Argonne National Laboratory and the Radiation Laboratory of the University of California, have made valuable contributions to basic radiochemical and physical techniques.

Distribution of deuterium, both gas and oxide, is being handled ably by the Stuart Oxygen Company of San Francisco. The deuterium oxide was produced by other facilities under the Manhattan Project program.

It is appropriate to add here that the Atomic Energy Commission is keenly aware how important the proper availability and distribution of isotopes is to scientific, technical, and medical progress. So far as is compatible with the Atomic Energy Act, which gives it a virtual monopoly of the distribution of many isotopes and charges it with maintaining certain controls, the Commission will promote a program that will be of increasing benefit to scientific advance and human welfare.

In closing I should like to add that the Commission is naturally much interested in the dissemination of information and in training which will advance the proper use of isotopes. This is indicated by the official participation here of many persons from Commission laboratories and by the routine declassification of information related to isotope applications.

It is well to recognize, however, that (1) other important Commission activities are in serious competition for Commission personnel and facilities; (2) the Commission's informational and training activities operate under limitations to which educational institutions are not subject; and (3) much more research with distributed isotopes is done outside Commission laboratories than inside them. Thus educational institutions are in a position to take the lead in promoting education and training in isotope applications. The University of Wisconsin is to be congratulated on the timely and valuable contribution in that direction made by this excellent Symposium. (Aebersold 1948)

A later paper by Aebersold (1956) gives considerable perspective for the uses of the radioisotopes produced. It was an era of almost missionary zeal.

Note that the program included stable as well as radioactive isotopes and involved facilities other than the Clinton Laboratories reactor. Prices paid were nominal in most cases. By August 1, 1966, there had been over two hundred thousand shipments of radioisotopes involving over 5.5 million *curies* of radioactivity. Another 2.5 million *curies* went out from other AEC installations (Brookhaven, Mound Laboratory, the Savannah River Project, and Idaho operations).^(a) The obvious crescendo was associated with the official "Atoms for Peace" program and included a large number of individual physicians and researchers who had been trained and met the licensing requirements of the AEC. Much of the training was provided by AEC through intensive short courses at Oak Ridge, summer institutes at many laboratories, and formal degree programs at universities.

The cyclotrons did not shut down during this period. Many isotopes can be prepared satisfactorily only with the cyclotron; others are best prepared in the nuclear reactor. However, it was the availability of large quantities from the reactor that took the lid off the development of therapeutic applications.

(a) Some of this information is from a manuscript for a speech given about 1967 by C. L. Dunham, M.D., Director of the Division of Biology and Medicine, AEC, and kindly supplied to me by Dr. H. D. Bruner, one of Dunham's colleagues, who may well have helped write the speech.

2. Radioiodine

We saw in chapter 5 the development of radioiodine uses by the Berkeley and the MIT-MGH groups in the prewar years (Hertz, Roberts, and Evans 1938).^(a) Its remarkable affinity for the thyroid gland has not been equaled by any other isotope toward any organ. As soon as sufficient quantities were available, it was pressed into service for therapy of thyroid disorders. Pioneered by the Berkeley and MIT-MGH groups, even before large quantities were available, iodine, principally ^{131}I , has taken its place beside surgery in cases of chronic overactivity of the thyroid gland (thyrotoxicosis, Graves' disease).

Perhaps the easiest way to see what was done with iodine before World War II is to consult chapter 5 herein and Marshall Brucer's essay, "Genesis of Thyroid-Radioiodine . . ." done as part of the series of *Vignettes of Nuclear Medicine* (Brucer 1978). For the status immediately postwar, the collection of papers from the first postwar iodine symposium directed largely toward clinical uses held at the then-new Brookhaven National Laboratory (BNL) in July 1948 (BNL 1948) gives reviews done in an informal atmosphere.^(b) This latter volume includes, particularly in the paper by R. W. Rawson (Memorial Hospital, New York), a cogent review of the "firsts" in this field.

Iodine in large doses is especially useful in cases where risk of surgery is great, for example in cases of chronic heart difficulties associated with the overactive thyroid. The cure rates have been impressive. Nevertheless, it is our duty, as it was of the attending physicians, to consider any untoward toxic sequelae. This work was begun in MED and AEC installations, and there is an ample literature. We will consider some highlights.

Immediate side effects can be related to local irradiation of surrounding tissues. Sometimes there is temporary exacerbation of the hyperthyroidism, especially after large doses of ^{131}I . A more important, indeed the chief undesired effect following iodine treatment is the development of underactivity of the thyroid (hypothyroidism). This is not surprising when one realizes that the doses used generally cause complete ablation of the gland. The occurrence of

(a) While there is no question that the original animal work was done by the MIT-MGH group, and the first uses of iodine in human diagnosis occurred at Berkeley and at MIT-MGH, it is possible that therapeutic uses of ^{131}I began independently in other places as well. For example, Dr. William F. Bale recalled in personal interview (Bale 1979) the case of a small boy at Rochester with thyroid cancer. The surgeons had removed as much tissue as possible, but there was still a tumor underneath where they could not work. They thought of ^{131}I treatment, but the University of Rochester's cyclotron as then constituted could not make enough of the isotope. Dr. Bale was going to St. Louis for a scientific meeting (about 1945) and persuaded people at Washington University's cyclotron (Professor Hughes) to run the machine all the time he was there to make enough radiotellurium for the purpose. It went back to Rochester in the baggage car on the same train as Dr. Bale. Immediately on arrival, they taught themselves some "hot tellurium" chemistry and had radioiodine on a scale never seen before at Rochester. The boy received several millicuries of ^{131}I and the tumor regressed. He later received a dose of ^{131}I via the Oak Ridge program. Fifteen years later (approximately) he was back to see Dr. Bale and was apparently in good health. This episode is described partly to indicate how the ideas spread or even arose de novo in different places, but primarily to show the lengths many nonmedical people went to in fostering what is now called nuclear medicine.

(b) And the price for the proceedings was listed as forty-five cents!

hypothyroidism is about 20% in the first year and rises gradually to about 50% at fifteen years (Chapman 1965). The same effect appears after surgical ablation, but the higher doses of ^{131}I appear more prone to produce hypothyroidism. This is illustrated in figure 20.5, taken from a definitive review by Maxon et al. (1977) working at Cincinnati.^(a) This induced hypothyroidism is not a serious problem so long as replacement therapy remains effective and easily available.

FIGURE 20.5. Probability of becoming hypothyroid with a single treatment of ^{131}I for Graves' disease. The numbers on the curves show the ^{131}I dose in microcuries per gram of thyroid. From the Cooperative Thyrotoxicosis Follow-up Study. (Redrawn from Maxon et al. 1977. Reprinted with permission of the American Journal of Medicine, New York, copyright 1977.)

There was, of course, ample experimental work with animals to precede or extend to higher doses all of the experience with patients. Special mention should be made of prewar work at Berkeley (remembering that the original work of Hertz, Roberts, and Evans was done with rabbits at MIT-MGH in 1938), Hamilton, Soley, and Eichorn (1940); Hamilton and Soley (1940); and the post-war work of Durbin et al. (1958a) on the long-term sequelae of massive doses of ^{131}I in rats; and of Watts and Durbin (1956) on distribution and acute effects. It was quite clear that the high levels (10 to 90 $\mu\text{Ci/g}$) retarded growth and destroyed the thyroid. There was, in addition, chronic renal damage, atrophy of the spleen, lymph nodes, and thymus and earlier appearance of mammary tumors, although the incidence was not related to ^{131}I dosage. In later work, Durbin

(a) The Cincinnati General Hospital and the University of Cincinnati have been a major center for thyroid work for many years under the capable leadership of Eugene Saenger.

et al. (1961) concluded that these and other sequelae involving the anterior pituitary gland and adrenal were consequences of *both* radiation damage and deep and prolonged endocrine deficiency. Thus, we see that the toxicologic enterprise had been doing its bit. There was much more.

Particular concern developed around the possible increased occurrence of leukemia in patients who had had thyroid ablation with radioiodine. It was already known that thyrotoxicosis patients had an increased risk of leukemia. Would the radiation treatment amplify this tendency?

This concern led the Bureau of Radiological Health of the U.S. PHS to set up a formal retrospective epidemiologic study called "The Cooperative Thyrotoxicosis Therapy Follow-up Study." Over thirty-six thousand treated patients and suitable controls were included. There were twenty-five medical institutions in the United States and one in England that provided data. The results are nicely summarized by E. Tomkins (1970) and by Saenger, Thoma, and Tompkins (1968). The incidence rate of leukemia, age-adjusted, was eleven per one hundred thousand patient years in the ^{131}I -treated patients and fourteen per one hundred thousand patient years in those treated by thyroidectomy. While this does not necessarily mean that surgical ablation is *more* likely to result in leukemia, the evidence clearly does not implicate the radioiodine treatment.

The same general conclusion, although somewhat more guarded, was drawn from a study in the United Kingdom done earlier (Pochin 1960).

A much more difficult situation surrounded the plans for therapeutic uses of radioiodine for the treatment of thyroid cancer. Early work in a number of laboratories showed, using tracer-level administrations, that the uptake of iodine by tumors of the thyroid was quite unpredictable. Some tumor types took up iodine almost as avidly as normal thyroid tissue. Others took up almost no radioiodine. The same held for metastases of the various tumor types. A pattern was gradually worked out so that radioiodine therapy could be applied to those tumor types that would take up iodine. In such cases, the nodules regressed, the bone pain that often accompanies thyroid cancer disappeared, and the indication of lesions on the scan also disappeared. Thus, the results can be positive, and the effort has its place, frequently as an adjunct to surgery. However, there is not the universal effectiveness seen in the treatment of toxic goiter.

Much effort has been expended to find out why some tumors take up iodine and others do not; also to change recalcitrant ones into receptive ones. The effort has given some leads but no final solutions.

The other side of the coin is whether or not radioiodine treatment can induce cancer in glands treated for other purposes. We looked at the low doses associated with fallout or routine releases from nuclear energy installations in earlier chapters. The doses used in therapy are, of course, much higher. There is a small but finite risk involved, higher in children than in adults, as shown by a number of surveys that we do not have space to elaborate upon. The appendix on iodine of the AEC-Reactor Safety Study (Reactor Safety Study 1975) done partly by Maxon at Cincinnati, the review by Maxon et al. (1977), the review by UNSCEAR (1977), and a Swedish study (Holm et al. 1980) all point in the same direction, but only the bold will decide whether or not risks of the order found are "acceptable." The chief problem is those persons irradiated at an early age who have many decades ahead in which effects could be manifested. Also, the long-term view may be more problematical for those receiving moderate doses that do not ablate the gland than for those receiving doses that caused

ablation. A very conservative view (Emerson and Braverman 1980) in a very conservative journal suggests it may take several generations to investigate the more subtle long-term impacts.

An overview of risks derived tentatively by Maxon et al. (1977) gives us a status report, even though the absolute values of the numbers are not settled. They are shown in table 20.4, which is taken from the Maxon paper.^(a)

TABLE 20.4. Absolute Risk* of Thyroid Abnormalities After Exposure to Ionizing Radiation

— Internal Irradiation (¹³¹ I) —			
Thyroid nodularity			
Children	9,000	0.23	0 to 0.52
Adults	8,755	0.11	0.06 to 0.15
Thyroid cancer			
Children	9,000	0.06	0 to 0.16
Adults	8,755	0.05	0.038 to 0.066
Hypothyroidism			
"Low dose"—children	<10 to 1,900	4.9‡	3.9 to 22.9
"High dose"—adults	2,500 to 20,000	4.4	2.8 to 7.6§
— External Irradiation —			
Thyroid nodularity in children	0 to 1,500	12.3	4 to 45
Thyroid cancer in children	0 to 1,500	4.2	0.9 to 17.3
Hypothyroidism in adults	1,640	10.2	0 to 25

*In number of cases per million persons per rem per year.

†Unless otherwise indicated, the risk range was determined by using the assumption that the number of cases, n , out of the population at risk represents the true mean of a Poisson distribution. The range is then estimated by using $n \pm 2\sqrt{n}$ in the calculations to establish the 95 per cent confidence level.

‡Threshold of 20 rem.

§The value of 4.4 is taken from the mid-point of the dose range in question.

||In these cases, the risk was determined from the slope of the linear regression line. The range was estimated from the extreme data points, which provide the lowest and highest slopes.

Source: Reset From Maxon et al. 1977. Reprinted with permission of the American Journal of Medicine, New York, copyright 1977.

Several important points can be derived from this summary table:

1. The difference between children and adults is marked for the development of thyroid nodularity but not so large for thyroid cancer induction.

(a) The substance of this paper and other aspects are contained in a recent NCRP Report (NCRP 1985c) produced by the task group of which Dr. Maxon was chairman.

2. The risks of developing hypothyroidism appear higher than the risks of either nodules or cancer.
3. External radiation (x rays) is, in general, more risky than radioiodine (^{131}I).

This last point has been noted in animal work also (e.g., USSR work quoted by Maxon) and seemed to be about to become a maxim. Indeed, possible explanations, most of them referable to a dose-rate effect, have been suggested. Very recently, a comparison of ^{131}I and *localized* irradiation of the thyroid and pituitary glands of Long-Evans rats (Lee et al. 1982) has found no differences in effectiveness. Only still further work can settle the matter. There is much evidence for an extra effectiveness of external sources^(a) and there are some problems with the study by Lee et al.

The chances for some sort of untoward effect of large doses of radiation to the thyroid are certainly not negligible. The benefits of the treatment may more than compensate for the risk, but judgments need to be made quite regularly and carefully.

On the diagnostic side, where iodine is used either as the inorganic ion or incorporated in special compounds (e.g., iodinated rose bengal), the doses are very low and getting lower each year. While the linear no-threshold extrapolation (chapter 16) predicts a finite risk at any dose, the chances of significant long-term effects *in a given individual* are likely to be unmeasurable. Only by considering large populations can the probabilities of toxic effects be approached.

A picture that any book concerning the history of radioisotopes would be incomplete without is shown in figure 20.6. This shows a little girl at Berkeley having her thyroid radioiodine content counted with one of the old clumsy Geiger-Müller counters. It was published in 1942 by Joe Hamilton.

FIGURE 20.6. Early arrangements for counting activity of radioiodine in the thyroid gland, about 1941. (From the files of Dr. J. Hamilton, courtesy of Dr. P. W. Durbin, Lawrence Berkeley Laboratory.)

3. Astatine

The story of astatine took place entirely in one laboratory, the University of California at Berkeley. Astatine was isolated in 1940 by transmutation of bismuth by alpha particles at 32 MeV in the 60-in. cyclotron at the Crocker Laboratory (see chapters 6, 7, and 8). It had properties of the halogen group, and its chemical, physical, and nuclear properties established it as element 85. It was first called "Eka-Iodine." The name astatine was derived from the Greek word for

(a) This extra effectiveness is reiterated in the cited NCRP Report (NCRP 1985b), but it is lowered to a factor of only three.

"unstable." It emits alpha particles, the only synthetic radioelement to do so up to that time, of about 6.9-MeV average energy and an 80-keV x ray, handy for in-vivo counting, with a half-life of only 7.3 hr.^(a)

As soon as possible, Hamilton and his group investigated its metabolism in guinea pigs and found that it behaved as a halogen should. It was taken up with considerable avidity by the thyroid gland (Hamilton and Soley 1940). The uptake was less than half that of iodine, but still enough to suggest possible usefulness in therapy. This was particularly intriguing because of the high effectiveness, known qualitatively even then, of the alpha particle. Also, its excretion rate, greater accumulation in hyperplastic (i.e., "thyrotoxic") thyroid glands, and other properties stimulated its active consideration as a substitute for radioiodine in therapeutic applications. This led to a flurry of activity with animals at the Crocker Laboratory as a prelude to human trials.

A summary was produced in 1953 as one of the University of California Publications in Pharmacology series (Hamilton et al. 1953). There is extensive autoradiographic information, along with biochemical determinations and detailed studies of effects in rats and monkeys. The metabolism of ^{211}At and ^{131}I resemble each other, primarily in their considerable deposition in the thyroid gland. In almost all other tissues, there was more astatine than iodine. This indicated that the "figure of merit" for astatine would be much lower than for radioiodine. Nor was the concentration in thyroid as high relatively as that of ^{131}I . Thus, the possibility of radiation damage to other tissues appeared greater. Nevertheless, the localization was still highly selective and promising.

The effects work showed that astatine could produce profound effects in the thyroid gland with no injury to the immediately surrounding tissues, including the parathyroid gland, an advantage over iodine. There were easily measurable effects on the body weight, white cell counts, etc., which recovered fairly completely.

In 1954, there was a series of reports from Berkeley on the astatine work. First let us examine the further animal physiology and pathology. Acute lethal dose of ^{131}I was about 85 $\mu\text{Ci/g}$ (median lethal dose in 60 days), while that for astatine was only 1.12 $\mu\text{Ci/g}$ (Hamilton, Durbin, and Parrott 1954b). The amount of tissue destruction was large. At lower doses (e.g., 0.4 to 0.8 $\mu\text{Ci/g}$), the incidence of mammary tumors rose significantly in Sprague-Dawley rats beginning 135 days after a single intravenous injection (Hamilton, Durbin, and Parrott 1954c).

Accumulation of astatine by the human thyroid was measured in this period (Hamilton, Durbin, and Parrott 1954a,b). It was considerable—relatively higher than expected from the experiments employing rats. The uptake was related to the functional condition of the thyroid, much as is the uptake of radioiodine. Also, it seemed to be correlated with the amount of stable iodine already present in the gland. One patient with a thyroid tumor (papillary adenocarcinoma) was measured. There was no measurable accumulation of astatine in metastases to the lymph nodes from this tumor.

An interesting contrast between iodine and astatine was seen in the effect of an antithyroid drug like propyl thiouracil (Durbin, Hamilton, and Parrott 1954a).

(a) Actually about twenty isomers of astatine were identified. The one of most interest is ^{211}At . Astatine-210 has a convenient half-life also, but it decays to the very radiotoxic ^{210}Po (see chapter 4) and is thus useless for therapy. Astatine-211 has two modes of decay, one to stable ^{207}Pb through ^{211}Po , the other to ^{207}Bi and slowly (half-life fifty years) to stable ^{207}Pb .

Whereas uptake of iodine is greatly reduced or blocked by such drugs, the uptake of astatine was enhanced, in the rat at least. However, the contrast did not extend to the administration of thyroxine, where the two halogens behaved similarly (Shellabarger et al. 1954).

In the 1954 period, two UCRL reports on methodology were issued. One (Parrott et al. 1955) concerned the production and isolation of ^{211}At . The other (Durbin, Hamilton, and Parrott 1954b) concerned the codetermination of iodine isotopes and astatine in tissue.

Joe Hamilton presented a summary of the astatine story at the first Atoms for Peace Conference in Geneva, Switzerland, in June 1955 (Hamilton et al. 1955). There was no judgment made on its relative therapeutic potential.

Some interesting permutations of the astatine work were done in the succeeding years. For example, it appeared that permanent structural damage remained in the thyroid after astatine treatment, even though function, as measured by radioiodine uptake, had apparently returned to normal (Durbin et al. 1957). Durbin et al. (1958b) carried on with the animal work and produced a long and detailed study of the induction of tumors in the rat by ^{211}At . There were several varieties of mammary tumors, both benign and malignant, and tumors of the pituitary. The calculated radiation doses were on the order of 50 rad to mammary tissue and 240 rad to the pituitary. If multiplied by an appropriate RBE factor, these doses may have been sufficient to produce the tumors. However, the authors did not feel the information was sufficient for them to separate out a radiation effect from an endocrine effect and concluded it was both.

There was also considerable weight reduction of the ovary that was uniform regardless of treatments for the endocrine disturbances. Although the calculated radiation dose is not large, the authors felt this effect might be radiation-induced to some degree.

With the death of Joe Hamilton of leukemia in 1957 and the somewhat discouraging incidence of various forms of tissue damage, the work slacked off. Patricia Durbin, C. Willet Asling, and others of the team continued mechanistic studies, but there seems not to have been much push for any therapeutic trials. Asling et al. (1959) demonstrated that astatine concentrates in mammary tissue of the rat and is secreted in the milk. These phenomena occur also with iodine, and the authors do not speculate as to whether or not the evidence made them lean more toward a radiation origin of the tumors reported earlier.

In 1964, Dr. Durbin and workers at Columbia University joined forces for work on the pituitary tumors (Yokoro et al. 1964). They concluded that direct irradiation played a major role in the induction of these tumors.

Here the story ends. There was no formal statement that the toxicity of astatine discouraged its clinical use. Yet, it seems clear that we see here an instance where great promise for therapy was negated by undesirably high concentrations of the element in normal tissues and damage at relatively low doses when compared to the isotopes it was sought to improve upon.

4. Radiocolloids and Microspheres

In earlier chapters, we described the importance of the formation of colloids to the distribution of and site of the effects of radioactive materials. We saw that many radionuclides that exist as molecules or ions under their usual conditions of handling, e.g., low pH, absence of coupling agents, etc., were prone to undergo hydrolysis reactions and to form aggregates at the relatively high pH of body fluids. Since the RES, with cells located primarily in spleen, liver, bone

marrow, and the lymphatic system, regards these particles as foreign bodies, they are phagocytized and frequently sequestered in one or more of these organ systems. The toxic sequelae of such depositions are frequently referable to this process, as well as to trapping of large aggregates in blood vessels or lymphatics.

It is not surprising that these properties were looked upon as possible tools for medical uses of radionuclides. As the work on inorganic ions progressed, and few substances showed the remarkable ability of iodine to localize in tissue, the affinity of the RES for colloids looked more and more promising. It was not an easy way to go, for there were many problems. However, the usefulness, particularly for scanning, has grown to the point where for some organs, e.g., liver, radioactive colloids are among the most frequently used means for imaging and measuring blood flow.

Much of the work in the formative periods was domiciled in the AEC laboratories investigating radioisotope toxicology. Colloids were, of course, known and appreciated in biological systems in the 1930s, if not before. In addition to Thorotrast and thorium dioxide, there was interest in colloidal calcium phosphate, chromic phosphate, and many others. However, the overt use of colloids for localizing radiation doses began at Berkeley a bit before the end of World War II. Hardin Jones and colleagues from the Donner Laboratory described a method for distributing beta radiation to the RES in 1944 (Jones, Wrobel, and Lyons 1944). In 1949, the Berkeley group gave chemical principles and methods for the preparation of colloids of yttrium, zirconium, columbium, and lanthanum (Gofman 1949) and the controlled selective localization of these in bone marrow, liver, and spleen (Dobson et al. 1949).

Why were these rather unusual elements chosen? They have a tendency, like many elements in the rare earth group, to form colloids, and it was relatively easy to produce different types of colloids with them. Also, they possess among them (three yttrium isotopes, three zirconium isotopes, two columbium isotopes, and one lanthanum isotope) a variety of nuclear properties from pure beta emitters, through mixed beta-gamma emitters, to pure gamma emitters. The objectives of the work were both diagnostic and therapeutic uses.

It soon became apparent that particle size played an important role in both their localization and clearance. This is reminiscent of the large enterprise we reviewed in the chapter on inhalation toxicology. However, the interest here lay in blood clearance rates, rather than lung clearance. "Relatively large"^(a) colloids—as determined by presence of a Tyndall effect and laborious counting in a hemocytometer—tended to localize in liver and spleen. Very little got to bone marrow, probably because the liver and spleen screened out the particles. Isotopes of zirconium, columbium, and yttrium were most convenient for this use. The blood disappearance was characterized by an initial very rapid phase, followed by a slow phase with a half-life of over two hundred minutes (remember the similar behavior we saw in the toxicologic work?).

An "intermediate size" of both yttrium and zirconium could be prepared by fairly easy manipulations. Up to 60% of this left the blood so rapidly it was gone before the first blood sample could be taken. The rest left with a constant half-life of about forty-four to fifty-five minutes (up to seventy minutes of

(a) In those days, particle size distributions in aqueous systems were very difficult to quantitate except grossly by such measures as turbidity or counting on the microscope.

measurement). Liver was the primary deposition site for these, and bone marrow was second, ahead of spleen: In the case of yttrium, bone marrow was first.

The next steps are hard to follow. There was a gradual development. The uses of radiocolloids grew and extended. Ample detail can be found in the several textbooks and in the symposia cited (see, for example, the chapter by Muller [1965] from Switzerland in the Blahd textbook). The rare earths did not play as predominant a role as they did earlier. Instead, the emphasis was placed on radioactive colloidal gold^(a,b) and chromic phosphate. The former especially became very useful for direct application to sites of cancer because it remained in place almost indefinitely. Colloidal chromic phosphate was investigated in depth and used widely (Dobson et al. 1966). Ovarian tumors were treated extensively with radiocolloids by Muller, but many other localized tumors were also treated, especially palliatively.

Many workers preferred to have the radioactivity in an organic molecule that could be broken down more rapidly by tissue enzymes than the inorganic complexes. Rapid decomposition was especially desirable if the purpose was in-vivo counting by scanning techniques. Human serum albumin can be aggregated and labeled with various radionuclides, e.g., ^{131}I , ^{125}I , ^{51}Cr . The aggregation process is fairly simple, heat treatment and pH adjustment, and suspensions of particles from less than 10 to 200 μm (0.01 to 0.2 μ) in diameter are easily produced. A pioneer in this area was Dr. George Taplin. He worked early at the University of Rochester and for over three decades at the AEC Project at the University of California at Los Angeles (UCLA) and at the UCLA hospitals. He contributed many innovations to both nuclear medicine and radioisotope toxicology. He was keenly aware of the possible untoward effects of introducing aggregates that could block pulmonary or cerebral blood vessels. The UCLA group, along with others around the country, did fairly extensive animal experiments to check on the possibility of such complications. The early colloid preparations had fairly low specific activities, and the margin of safety as measured in the animal experiments was about fiftyfold. This was not considered enough to chance cerebral embolism, and clinical trials were deferred.

Henry Wagner at The Johns Hopkins University in Baltimore helped solve the problem by introducing aggregates with much higher specific activity (e.g., 1,000 μCi of ^{131}I per milligram of albumin). The developments at UCLA and at The Johns Hopkins are described in the chapter by Taplin et al. (1966).^(c) They checked out the possibility of cerebral complications in both dogs and monkeys and related it to the amount of material injected. By using the higher-specific-activity material (available commercially by then), the margin of safety for a lung

(a) Colloidal ^{198}Au preparations were first made by Paul Hahn (1956). A product of Dr. George Whipples's group at Rochester (chapter 5), Hahn went to Vanderbilt and later to Meharry Medical College. His book, *Therapeutic Use of Artificial Radioisotopes*, gives much important information on the development of the field.

(b) Seeds of radiogold were also used for implantation as a replacement for radon seeds (Henschke, James, and Myers 1953, 1954). This does not, of course, have anything to do with radiocolloids.

(c) Dr. George Taplin also did much pioneer work in lung diseases and knew a great deal about the development and uses of medical aerosols. He was a member of the inhalation toxicology panel of the original National Academy Committee on the Biological Effects of Atomic Radiation (BEAR); see chapter 16. He also developed methods for diagnosis of renal disease (see chapter 13 in Blahd 1965). His death in full career is a saddening note.

scan was considered to be greater than two thousand, assuming that less than 1 mg of aggregate was injected. The clinical work went ahead. Later clinical follow-ups at Harbor General Hospital in Los Angeles showed no objective or subjective reactions in over fifteen hundred scans. (The number is, of course, much greater now, but the techniques are different, as we will see in part B of this section.)

For greater localization in the bone marrow and less entrapment in liver and spleen, very small particle sizes are useful. Colloidal gold at $5\ \mu\text{m}$ ($0.005\ \mu$) has been suggested in treatment of chronic leukemia (Muller 1965). Naturally, the hazard of undesired trapping in blood vessels and embolism is further reduced by such a procedure. (Note that the particle sizes we are talking about here are very much smaller than those of most interest in inhalation toxicology—chapter 9.)

The Oak Ridge Institute of Nuclear Studies (now Oak Ridge Associated Universities), a separate entity from ORNL and financed indirectly by AEC and successor agencies through a consortium of universities, has long had a strong medical research program in both external radiation and radioisotopes. Partly because of nearness to the reactor and partly because of general interest, a fairly large program was developed on the rare earths (chapter 8). Some quite esoteric elements were checked out for possible uses in nuclear medicine, especially members of the lanthanide series, along with better known ones. The former included gadolinium, dysprosium, holmium, and lutetium. An excellent summary of the colloid chemistry involved and behavior of the colloids in animals can be found in a paper by Kyker and Rafter (1966) in the radio-pharmaceuticals symposium. It is of interest to note the extremely low concentrations at or above which immobilization of these elements is complete, viz., 10^{-7} mole/kg. All that is needed is to get it where it should stay!

For reasons that are not entirely clear, these entities did not find as much clinical favor as isotopes of gallium, on which the Oak Ridge Institute lavished concentrated attention. We will review this in a following section.

Finally, we come to the artificially produced plastic and ceramic microspheres. These were introduced in 1960. In chapter 9, we reviewed the use made of these (the plastic variety) in connection with the "hot particle" problem in inhalation toxicology. We mentioned that they were manufactured by the 3M Company in Minneapolis "for medical uses." The medical uses were to label the spheres and use them as tracers or for therapy in the way we have been discussing for colloids. They can be made in a large number of sizes and very high specific activities can be attained. Grotenhuis (1966) describes their properties and availability, and part of the discussion of the treatment of malignant disease with radiocolloids by Muller (1965) refers to their use. However, since they are essentially indestructible and would be around long after the radioactivity had decayed away, their use for diagnostic scans, which employs small amounts, may be preferable to the application of large amounts in therapy.

5. Radiophosphorus

The isotope ^{32}P was, as we have seen, among the earliest to be used for nuclear medicine and tracer chemistry. We need to say little more than we already have to be sure its position is made clear.

Since phosphorus is an integral part of most metabolic pathways, it is not surprising that it has a tendency to be labile. By today's criteria, ^{32}P is quite

energetic and of long half-life. Nevertheless, in addition to its early use for the treatment of leukemia and polycythemia vera, it has found use for tumor localization. Of interest is the fact that some types of thyroid nodules that fail to take up radioiodine do take up radiophosphorus. Many rapidly growing tumors can be differentiated from benign or slowly growing malignant tumors by their incorporation of radiophosphorus. Evidently, the metabolic pathways of some tumor types are especially demanding of phosphorylated intermediates.

On the treatment side, perhaps the history that is most pertinent to the period we are studying is the chapter by Shkurkin and Lawrence (1965) from Berkeley. As the work unfolded, the expectation for curing leukemia withered. Phosphorus-32 is not useful for acute leukemia. However, it is still used for some chronic types. The best results have continued to be with polycythemia vera, where treatment can be expected to result in a normal life expectancy. There is no question that the unwanted radiation dose to normal tissues has been one of the limiting factors for this radionuclide in other therapeutic modalities.

There are those who feel that long-term follow-ups for sequelae from the use of agents as powerful as ^{32}P have not been sufficient. Dr. Helen Woodard at Sloan-Kettering Institute in New York is one of these. In a personal letter to the author summarizing her long experience, she quotes many instances of severe bone marrow depression following use of ^{32}P , ^{35}S , etc. Sometimes treatment had to be suspended after what seemed to be rather small doses. While these effects are mild next to many of the really toxic radionuclides we have reviewed in this book (the microcurie doses of ^{32}P used would have been fatal with an element like plutonium), Dr. Woodard quotes an instance of aspermia in a man who received $310\ \mu\text{Ci/kg}$ of ^{32}P in six months, even though he had only mild and transitory bone marrow depression. The aspermia occurred *nine* years after the exposure. While there are too many other possible causes to be sure the ^{32}P treatment did it, Dr. Woodard urged much more careful follow-up procedures over long periods (Woodard 1971). This is an underinvestigated part of radioisotope toxicology.

Finally, although the toxicologic aspects are important to us, the story of ^{32}P also raises many more basic questions. Whether a given tumor type takes up the radionuclide or not is, at present, unpredictable except by a vague linkage to rate of growth. It is a commentary on the complexities of tumor biology and our knowledge of the basic biochemical processes that we must still be essentially empirical in these matters.

6. Gallium

We devote space in this section on specifics in the 1948 to 1966 period to gallium, not because of its paramount importance to either tracer chemistry or nuclear medicine, but because it occupied the attention of many AEC and related workers in the radioisotope toxicology field. Gallium was proposed for use as a reactor coolant at Oak Ridge (Hayes 1966), and radioisotopes of it were readily available there. In the late 1940s, Dudley and coworkers (Dudley, Maddox, and La Rue 1949; Dudley, Imirie, and Istock 1950) found that gallium (the nuclide ^{72}Ga) concentrated where new bone was being formed and thus might be a good marker for tumor sites and even a therapeutic agent. The results of both diagnostic and therapeutic trials at the then-new Oak Ridge Institute of Nuclear Studies (later Oak Ridge Associated Universities) and the Oak Ridge Hospital were, however, disappointing (Brucer, Andrews, and

Bruner, and others 1953; King, Brady, and Dudley 1952; Dudley, Markowitz, and Mitchell 1956). Despite localization in tumor sites, even before roentgenographic changes were evident, the therapeutic results were not consistent. Also, the photons from ^{72}Ga were too energetic for efficient scanning.

Later, interest in gallium was rekindled by the introduction of a generator "Cow" that produced ^{68}Ga from ^{68}Ge . This isotope has a sixty-eight minute half-life, and it decays primarily by positron emission. It found use when chelated with EDTA (see chapter 19) as a brain-scanning agent and in the citrate form with added stable gallium as a carrier for bone scanning (Edwards and Hayes 1972). However, the need for the carrier (to produce adequate skeletal uptake) generated concern for potential chemical toxicity, and there was considerable retention in the gut. Acceptance was therefore not widespread.

Still later, another isotope of gallium, ^{67}Ga , attracted interest (Comargo et al. 1979). When given intravenously as the citrate, this radionuclide seemed to localize in the lesions of Hodgkin's disease (Edwards and Hayes 1972). It has a longer half-life than ^{68}Ga , viz., seventy-eight hours and does not require a carrier. It seemed to be free of untoward side effects.

The primary reason for interest in these gallium isotopes was their uptake by tumors—again in a very selective fashion. Furthermore, ^{68}Ga showed considerable nonspecific uptake by inflamed or infected tissues. Acute pyogenic abscesses are the most consistent in taking up ^{67}Ga . This has turned out to be a useful diagnostic tool for ascertaining by scanning techniques, the location of hidden pockets of infection. These uses have eclipsed the original idea of treating bone tumors with ^{72}Ga and provide an instance where toxicity interdicted one use but led to modifications of nuclides and their use for something else.

As with ^{32}P , we are left with the uncomfortable conclusion that we must be empirical about determining what type of tissue will take up the isotope and what type will not. The basic work to make such differences predictable is a challenge for the future.

The gallium work did give us, besides a diagnostic agent, much information on the role of carriers—such as we saw in earlier chapters. The tissue distribution can be quite different when the isotope is in the carrier-free state (^{67}Ga) or in the presence of carrier, or, as in the case of ^{72}Ga , at low specific activity, which means a higher concentration for the same radiation dose. As Hayes (1966) discussed, the amount in liver and spleen is quite different in carrier-free than in the carrier-present state.

7. Antibodies—The Immunologic Approach

We introduced the principles of this approach to therapy with radioisotopes in section I C of this chapter. The exquisite specificity of antibodies for cell and tissue types encouraged extensive laboratory investigations to try to work out the right system. The requirements are stiff. The antibody should preferably be specific for the malignant cells at issue. It must be possible to get it to the site, sometimes through barriers. The compound must be amenable to the process of labeling with a suitable radioisotope and not be too easily degraded by the radiation field required to deliver a therapeutic dose.

Our space permits a consideration of only two major projects attacking this problem: the one at the University of Rochester headed by William F. Bale, Irving L. Spar and their colleagues, already mentioned; and the project at the Roswell Park Memorial Institute located in Buffalo, New York, headed by David Pressman. The first was funded almost entirely by AEC, with a bit of help in the

last years from the National Cancer Institute. The second was not so clearly an activity of people who had formerly worked in radiation toxicology and radiation biophysics as had Dr. Bale and his group. It had support from several sources.

The Rochester work got started when Dr. Bale returned from his year of duty at AEC Headquarters, where he was concerned with many problems of radiation protection, including the uranium miners (see chapter 3). It took considerable courage to embark on an entirely new and complex field totally different from the instrumentation and biophysics that had been Bale's forte for many years.^(a) He soon persuaded Dr. Irving Spar, who had just completed a Ph.D. in biology with a thesis in genetics with immunological overtones, to join him. Later, Dr. Ralph Helmkamp, an organic chemist with much experience in synthetic organic chemistry, retired from his long-held post in the chemistry department at Rochester and joined Bale's group to undertake the difficult problems of labeling the complex antibody molecules. In addition, the group acquired an exceptionally capable set of technical associates and collaborators. Most of the group spent the rest of their scientific careers on this one problem.

A complete and informative review of the entire field, to the date of writing, was placed in one of the volumes in the series, *Advances in Biological and Medical Physics* (Bale and Spar 1957). The production of antibodies with "substantial organ and tissue specificity" is described. The preparation of antibodies against kidney, adrenal, lymphatic tissue, several other organs, and tumors is described in depth. Also described is the methodology for labeling antibodies with radioisotopes; usually ^{131}I . Much of the early antitumor work utilized anti-Walker tumor antibodies.

It was not easy going. Localization of labeled (iodinated) anti-Walker preparations was preferential for adrenal, ovary, liver, and spleen.^(b) The localization was a function of time, but there was always too much in blood and tissues other than tumor in these early experiments. Thus, too much of the activity was remaining in circulating blood, with resultant dose to tissues other than the tumor.

It was suggested that exclusion from the circulation of certain parts of the body not containing tumor might increase the relative dose to the tumor tissue. This would require complex procedures for isolation of segments of the circulation—not beyond the abilities of vascular surgery, but not to be undertaken lightly. It was also suggested that some of the information being obtained on protection of tissues against radiation by preparations from spleen, bone marrow, etc., might be used to increase the ratio of effectiveness for tumor versus other organs, despite the presence of unwanted radioactivity in the blood.

The work at Rochester continued well into the 1970s. There was concentration on fibrinogen and immunological uses of derivatives of it. However, this carries us further than we can go. The accumulating results were encouraging

(a) William F. Bale received the first Ph.D. degree given in Biophysics at the University of Rochester. At that time, it was an interdepartmental degree and included departments from the College of Arts and Sciences as well as the Medical School.

(b) Results are summarized in the review cited. Individual papers can be seen in the *Journal of Immunology*, several symposia, the *Proceedings of the Society for Experimental Biology and Medicine*, and University of Rochester Atomic Energy Project reports. Some are cited in the review.

enough to permit a few clinical trials. However, on balance, the degree of localization, as in so many other potential therapeutic procedures of these decades, was not sufficient for generalized therapeutic use. In the interim, a great deal was learned about the immunological processes investigated.

After his retirement in 1976, Dr. Bale went to the Georgia Institute of Technology, where he tried a different approach. We will review his ideas briefly in section IV C.

The Roswell Park work was largely immunological and concerned, among other things, antibodies against chemically induced rat hepatomas. It utilized ^{125}I in pair with ^{131}I for labeling purposes and autoradiography. The latter was important because the sites of antibody localization in tumor could be investigated at the cellular level.^(a)

A vignette of the problems of the field can be seen in a quotation from the Roswell Park work in the *Journal of Nuclear Medicine* in 1964 (Yagi and Pressman 1964). "...the localization of control protein or antibody is unpredictably variable in different tumors of the same individual or even different parts of individual tumors, depending on vascularity, stage of development, etc." (Yagi and Pressman 1964).

This somewhat pessimistic outlook set the pace for the field for many years. However, very recent (1980s) developments in immunology indicate it may be possible to increase localization greatly, and the field may be due for a resurgence (Cronkite 1982).

There were, of course, numerous uses of radioactively labeled antigens in both basic research and studies of pharmacodynamics (e.g., Korngold et al. 1953). However, these have not changed the general conclusions inherent in what we have seen thus far. But we should not forget that the tracer uses of labeled materials in immunology underlay the development of the extremely powerful tool, radioimmunoassay (to be discussed briefly in a later section).

8. Neutron-Capture Reactions as Therapeutic Tools

The principle involved in neutron-capture reactions is the production of radioisotopes *in vivo* by localization, preferably at a tumor site, of substances with high cross sections for neutron capture, and subsequent irradiation by a flux of slow neutrons. Likely substances to place *in situ* are ^{10}B , ^6Li , and ^{235}U . The first two produce alpha particles and a residual nucleus on capture of a slow neutron; ^{235}U fissions with release of considerable energy (162 MeV). The advantage of such a system is that there is no radiation until the external neutron beam is turned on, and it can be localized by the *collimation* and focus of the beam as well as by specific attachment of the fissionable substance. The problem is, as always, preferential localization of the substance in the tumor cells.

In the chapter on uranium (chapter 2), we examined briefly the collaborative effort between Dr. William Sweet of MGH and the Boston Veterans Administration Hospitals, and members of the Health Physics Division of ORNL using ^{235}U (see also Hursh and Spoor 1973, pp. 204-206). While the interest was partly in following the metabolism of the higher-specific-activity isotopes of uranium in man, the work also provided an opportunity to try the *in-situ* neutron-capture therapy. As we saw in chapter 2, the results were marginal.

(a) The Bale-Spar review gives thirteen references to Pressman's work.

At about the same time, Sweet appears to have also considered the use of boron (Sweet and Javid 1952). This was followed through a collaborative effort with Dr. Lee Farr, the first director of the Medical Division at BNL, which was then relatively new, and his collaborators (Farr 1955; Farr et al. 1954). Boron-10 was found to localize to some extent in the brain because it did not pass the blood-brain barrier. It was reasoned it might localize in tumor tissue of the brain enough to warrant a trial. A few patients seriously ill with brain tumors were given boron and then irradiated as locally as possible with a somewhat mixed neutron beam taken from the old graphite reactor at Brookhaven.^(a) Despite some evidence of localized effects, the results were discouraging. Too much boron remained in the blood (Cronkite 1982), and this was activated to carry radiation to many sites away from the one hoped-for localization. Also, the neutron beam was far from pure or easy to focus.

Bale and Spar allude to use of antibodies to carry ^{10}B or other isotopes useful for neutron-capture therapy. They calculated the degree of localization of the added isotope in the antibody needed to produce the desired dose in the region of antibody localization. For boron, each antibody molecule should have twenty-seven ^{10}B atoms attached. For ^6Li , the required number is seventy-three. Only for ^{235}U is the number small: 3.3 ^{235}U atoms per antibody molecule. Thus, we needed not only localization of the antibody at the tumor site, but attachment of sufficient atoms to capture the neutrons effectively.

Despite the problems of the early work, even the conclusion that the treatment may have made these particular patients worse, if anything, the development of reactors for medical uses continued. There were many reasons to think the techniques could be greatly refined and improved. Also, reactors could do many other things. Brookhaven eventually built a medical reactor, which has served for many years, but not predominantly for neutron-capture therapy. By this time, Lee Farr had gone elsewhere, but his pioneering ideas and those of his associates should not be discounted.

We will see some possible and some tested extrapolations to a much later period in section IV C. However, as part of this first era of *therapeutic intent*, we must conclude that the old bugaboo of selective localization put the neutron activation work on ice for many years. It did not inhibit very large advances in the tracer chemistry and basic science facets of the field.

9. Comments on the Earlier Years

Obviously, these were years of rapid progress. The workers and institutions identified with radioisotope toxicology played major roles in initiating, furthering, and controlling the safety of the developments. Radioactive isotopes became as commonplace in the clinical departments and in institutions devoted entirely to clinical medicine as they had been in biomedical research. By the middle of the decade of the 1960s, the impetus for new therapeutic uses began to wane, even though there was no paucity of ideas for isotopes, physical and chemical forms, and applications to therapy. A good overview of the status of *therapy* with radioactive isotopes at the end of this period can be seen in a 1968 review paper in the *Progress in Atomic Medicine* series by Wasserman and Glass (1968), Mount Sinai Hospital and School of Medicine. The portion of their summary table that concerns internal applications is reproduced as table 20.5.

(a) It was a somewhat heroic experiment since the patient had to be lifted to the top of the reactor in most unhospital-like surroundings.

A glance back through the developments we have cited in this section gives perspective on the large contribution of the major radioisotope centers supported by the AEC, the Manhattan Project, and, to a lesser degree, other government agencies in getting the work started and perpetuated.

TABLE 20.5. Isotopes Used in Therapy as of 1968

I. External Applications		
A. Teletherapy—External Gamma Ray Beam Units		
Cobalt-60		External beam therapy; deep-seated and other malignancies
Cesium-137		
Radium-226		
B. External Beta Radiation Units		
Strontium-90		Widespread superficial malignancies
C. Extracorporeal Irradiation Units		
Gamma: Cobalt-60, Cesium-137		Induction of lymphocytopenia and immuno-suppression; treatment of chronic leukemia
Beta: Strontium-90		
D. Interstitial, Intracavitary and Contact Therapy with Encapsulated Gamma Ray Sources		
Radium-226	Tantalum-182	Implantation of accessible malignant tumors, e.g., carcinoma of the cervix, carcinoma of the bladder, lymph-node metastases
Radon-222	Iridium-192	
Cobalt-60	Gold-198	
Cesium-137		
E. Interstitial Therapy with Isotopes Decaying by Electron Capture		
Iodine-125	Cesium-131	Implantation of tumors
F. Contact (Superficial) Therapy with Encapsulated Beta Sources		
Phosphorus-32	Sulfur-35	Treatment of selected dermatologic and ophthalmologic conditions
Strontium-90	Cerium-144	
G. Interstitial Therapy with Encapsulated Beta Sources		
Strontium-90	Phosphorus-32	Local tissue destruction, e.g., hypophysectomy, cordotomy, etc.
Yttrium-90	Gold-198	
II. Internal Applications		
A. Metabolic (Selective) Localization		
1. Isotopes administered in inorganic chemical form		
Iodine-131		Thyroid disorders, angina pectoris
Phosphorus-32		Polycythemia vera, chronic leukemia, thrombocythemia, osseous metastases
Sulfur-35		Chondrosarcoma
(Sodium-24)		Leukemia
(Strontium-90)		Malignancies of bone and bone marrow
(Calcium-45, 47)		Malignancies of bone and bone marrow
(Gallium-72)		Malignancies of bone and bone marrow
(Arsenic-76)		Chronic leukemia
2. Other forms		
Chelates—Yttrium-90		Immunosuppression; polycythemia vera; myeloma
Drugs—Tritium tagged		Malignant tumors
Neutron Capture Therapy—Boron-10		Glioblastoma multiforme

TABLE 20.5. Continued

B. Physical (Paraselective) Localization		
1. Intravascular administration		
a. Radiocolloids (intravenous administration)		
Phosphorus-32	Chronic leukemia; lymphoreticular malignancies	
Gold-198		
Yttrium-90		
b. Ceramic microspheres (intra-arterial, isolation-perfusion)		
Yttrium-90	Malignant tumors	
Phosphorus-32		
c. Short-lived beta-emitters (isolation-perfusion technique)		
Scandium-49		
Zinc-69	Malignant tumors	
Dysprosium-165		
2. Intracavitary administration		
Radiocolloids		
Phosphorus-32	Malignant pleural and peritoneal effusions, palliation and prophylaxis	
Yttrium-90		
Gold-198		
3. Interstitial administration		
Radiocolloids		
Phosphorus-32	Carcinoma of the prostate, cervix and breast; other malignancies	
Yttrium-90		
Gold-198		
4. Intralymphatic administration		
Radiocolloids		
Phosphorus-32		
Gold-198	Lymphoreticular malignancies, carcinomas, melanoma; palliation and prophylaxis	
Radioiodinated (Iodine-131) radiographic contrast material (Ethiodol, Lipiodol)		
5. Intra-articular administration		
Radiocolloids		
Gold-198	Recurrent synovial effusions

B. The Later Years—The Era of Ever More Scanning and Ever Shorter Half-Lives

There is obviously no sharp demarcation between the periods I have chosen to consider as eras. Many developments that underlay the second era began in the late 1950s and early 1960s, even before (Prinzmetal et al. 1949). Some were soon adopted and were expanding rapidly even by 1966. Nevertheless, the changing flavor of the enterprise was especially noticeable by the time of the symposium on radioactive pharmaceuticals at Oak Ridge, in the nature of the reports in the fast-growing *Journal of Nuclear Medicine* and the meetings of its Society, and in the symposia organized to look at new developments after the mid-1960s. As in the first era, many of the major developments came from laboratories supported by AEC or the U.S. PHS. However, their influence was more at the

beginning, less into operations of the 1980s, since nuclear medicine is now a major part of medicine and has much support from fees, third-party billings, and the like.

The *raison d'être* for the developments of this era, let us emphasize again, was reduction of the radiation dose to the patient. Thus, toxicologic considerations were the chief motivation. Increases in speed and convenience were the second major factor in the developments.^(a)

In this section, we will trace those developments of most pertinence to the central theme of this chapter and this book. We will see that therapy with radioisotopes played a more minor role in the planning—even though a few procedures continued to be of life-saving significance.

1. More Radioiodine

It was natural in these later years for there to be considerable concentration on the development of new isomers of iodine. We will review these in this section. However, as will be clear, these years saw iodine lose its place of supremacy to other, even more convenient, radionuclides.

At the June 1960 meeting of the Society of Nuclear Medicine held at Estes Park, Colorado, Dr. William G. Myers of Ohio State University suggested that ^{125}I should have significant advantages over ^{131}I for in-vivo scanning in thyroid-function studies. The lack of beta particles in its unique mode of decay (x rays plus Auger and internal conversion electrons) could result in considerable reduction (about one-half) in radiation dose. The dose rate was also reduced because of its longer half-life (sixty days).^(b) Yet, very adequate energies were available for tracing metabolic pathways of stable iodine. The abstract (Myers and Vanderleeden 1960a) was followed almost immediately by a complete paper (Myers and Vanderleeden 1960b) from the Departments of Medicine, Physiology and Radiology at the University Health Center and the Department of Physics of The Ohio State University. The ^{125}I could be obtained by bombardment of tellurium or antimony in a cyclotron. Some was produced by neutron bombardment in a reactor. The cited paper gives full details of generation, properties, and uses.

The low energies involved made this iodine isotope very suitable for labeling various compounds that had previously been labeled with ^{131}I .

A "merit ratio"^(c) could be calculated to highlight the advantages of ^{125}I over ^{131}I . Using 6.3 cm beneath the surface as the optimal distance, the merit ratio on the basis of relative photon energy was 3.7; on the basis of the quantum efficiency of the detector (100% for ^{125}I versus 50% for ^{131}I), it was 2.0; and the merit ratio based on the background counts in the particular detectors used (250 cpm for ^{131}I versus only 9.3 cpm for ^{125}I when shielded with a few millimeters of copper) was 27. Myers and colleagues multiplied these separate ratios to get a combined "merit" ratio of 200 for ^{125}I over ^{131}I .^(d)

(a) Tracer chemistry, of course, benefited also from some of the changes wrought. However, the primary changes were for increased convenience, speed, and accuracy of procedures already in place, not a shift in emphasis.

(b) Which also meant a more convenient "shelf" time.

(c) Ratio of usable signals to energy absorbed locally.

(d) Obviously, not all of this is resident in the isotope itself. Some is in the instrumentation that can be applied. It might be even better at less than 6.3 cm, gradually less as the depth of the source in tissue increases.

By the time Myers was named a Nuclear Medicine Pioneer^(a) by the Society of Nuclear Medicine (Wagner 1981), hundreds of millions of ^{125}I tests were being performed worldwide each year. A large number of these involve radioimmunoassay procedures for, as we will see, $^{99\text{m}}\text{Tc}$ was beginning to make inroads on the uses of iodine for in-vivo scanning.

At the Deutscher Röntgenkongress in 1964, Myers presented an excellent summary of the development and uses of ^{125}I in the period 1960 to 1964 (Myers 1965). This includes a reasonably complete literature summary, useful since this was, of course, not an Ohio State monopoly; along with extensive descriptions of ^{125}I 's special uses in labeled organic molecules.

However, Myers was not about to stop at ^{125}I . In May 1962, he described in collaboration with Hal Anger of the Donner Laboratory at Berkeley the virtues for scanning in nuclear medicine for ^{123}I . The radiation dose from this isotope in quantities suitable for diagnostic scans was only about 5% of that from ^{131}I (Myers and Anger 1962). This isotope has a thirteen-hour half-life. Therefore, its "shelf" time is less advantageous than ^{125}I 's. However, this difference in half-life is useful for double-labeling purposes. Also, it permits serial administration, and its 159-keV gamma ray is quite advantageous for scanning (see also Harper et al. 1963).

Unfortunately, ^{123}I was not then easily available in sufficient quantities and purity to supplant ^{125}I . An earnest effort was made to develop facilities that could meet the needs. This was part of the mission of the new biomedical cyclotrons such as the one at UCLA. At the dedication of this facility, Professor Glenn Seaborg (whom we met extensively in earlier chapters) included these statements:

Perhaps one of the most important medical isotopes this cyclotron will be making is iodine-123. . . There is no question about the utility of iodine-123. The question is whether enough can be produced in the present target-cyclotron configuration and then rapidly extracted for conversion into pharmaceutically suitable forms. If this alone can be accomplished, AEC's investment of men, machines and time shall have been a major success.
(Seaborg 1971)^(b)

For further detail of other isotopes of iodine (e.g., ^{121}I and ^{123}I), the reader is referred to Myers's historical and analytical summary given at the Oak Ridge symposium on radioactive pharmaceuticals (Myers 1966b) and to specific descriptions (Myers 1966a and 1974b). Here criteria are assigned for an ideal radioisotope in terms of the merit ratio for in-vivo diagnostic applications. The author does not single out one or even a few isotopes for special recommendation. Apparently, it is left for future developments to make these judgments.

Myers's historical review is also full of references to work by others. He worked closely with Professor I. Perlman, codiscoverer of ^{123}I and ^{121}I , with Hal Anger on ^{123}I and with others at the Donner Laboratory during the tenure of a visiting appointment to Berkeley arranged by Professor John Lawrence. It is

(a) In this honor he joined, among others, George Hevesy, Irène Curie, Ernst and John Lawrence, Lise Meitner, and his close and dear friend, Paul Aebersold.

(b) The expectations were met by the UCLA cyclotron in the early years. However, as commercial instruments became more numerous, active large users such as UCLA found it cheaper to rely on them. The local instrument could thus be reserved for research uses (Bennett 1979, 1981).

obvious, also, that close cooperation existed with the Isotopes Development Center at ORNL.

Although the orientation was medical, quite obviously the entire isotope establishment was involved. The health and medical physicists got interested too because of the potential for dose reduction. Note, for example, work by Sayeg and Preston (1973)^(a) given at a Health Physics Society Midyear Topical Symposium, "Health Physics in the Healing Arts." Also, the uses of these substances as tracers in all of biology received attention from the Feinendegen group already cited in connection with transmutation problems (Ertl, Feinendegen, and Heiniger 1970). Recently, the microdosimetric aspects of damage in DNA by ^{125}I have been investigated (Martin and Haseltine 1981).

Thus, despite the introduction of many new entities and techniques, the iodine isotopes maintained a predominant position for many years. The motivation, let us again be reminded, has been primarily reduction of patient dose, i.e., avoiding toxicity.

2. Nuclide Generators—Technetium Rises to Prominence

Even with the abundance of radioisotopes made available in the earlier years through the Isotopes Division of AEC, there were problems with the short-half-life isotopes. They either decayed away before they could be used or had to be dispatched at such high activities that shielding and shipping were major problems. With the pressure for more and more short-half-life material for diagnostic uses, the application of nuclide generators grew considerably.

The idea of a nuclide generator is, of course, old. The classic example is the separation of 3.8-day ^{222}Rn to make radon seeds from the 1,620-yr ^{226}Ra , accomplished by Failla in 1926. During World War II, application was made of shipping 12.8-day ^{140}Ba as a source of 40.2-hr ^{140}La . In principle, any short-lived daughter (24-hr or less half-life) coupled to a parent of half-life suitable for generating the daughter in reasonable quantity over a useful time period could become a nuclide generator. However, several criteria must be met (after Colombetti and Palma 1978):

1. It must yield a daughter with high radiochemical and radionuclide purity.
2. It must be safe and simple to operate.
3. It must be sterile and pyrogen free.
4. The product must be convenient for the preparation of radiopharmaceuticals.
5. It must be capable of multiple separations.
6. The daughter should have a half-life less than 24 hr. Otherwise, the radionuclide is better obtained directly from a commercial source.

A diagram of a very simple system is given as figure 20.7. This open system is primarily a laboratory type. Commercial systems are sealed to prevent entrance of bacteria into the column. They are tapped by fitting a closed container of sterile eluting solution and having a millipore filter in line with the outlet.

The absorber bed may be alumina, a Dowex resin, alumina with silica, etc. All of these rest in part upon the isotope separations techniques developed under the MED and carried forward postwar by the AEC. Few isotope pairs contain a gas phase, which made possible the first isotope generator—radon from radium.

(a) University of Kentucky Medical Center, Department of Radiation Medicine.

For obvious reasons, the process involved has been called milking, and the generators have been called "cows."

FIGURE 20.7. A chromatographic column used in open generator systems. Later systems were closed and sterile. (Redrawn from Richards 1966a.)

The first commercial application with real convenience was developed at BNL in 1954 for the ^{132}Te - ^{132}I system (cited by Richards 1966a). This was used more in Europe than in the United States, since 2.3-hr iodine did not catch on here. Brookhaven was instrumental in developing several other systems. The most widely used is the generator for 6-hr $^{99\text{m}}\text{Tc}$ from the parent, 2.7-day ^{99}Mo . Indeed, $^{99\text{m}}\text{Tc}$ soon made rapid inroads on iodine for many uses, since it has very favorable nuclear properties. Technetium was introduced for thyroid and other scans by Harper et al. (1964) as the pertechnetate. It emits no beta radiation, and the dose to the patient is quite low. Its use has grown enormously in the last two decades.^(a) A $^{99\text{m}}\text{Tc}$ generator is described in detail by Richards (1966b). The facility has the appearance of a large commercial production facility, and it was indeed used to supply national needs for a while.

Listings of generator systems in use in the mid-1960s, and those expected by Richards to be useful in the future, are given as table 20.6A and B. A "cow" for ^{68}Ga was developed by Yano and Anger (1964) because of the usefulness of positrons in the developing instrumentation.

It will be noted that the genesis of these devices goes well back into the period we have called "The Earlier Years." We place the discussion here because it was in the later years that the short-lived isotopes really came into their own. The development hinged considerably on parallel advances in measuring instruments. Together with accelerators, these generators made the later years a different era.

3. Accelerators

In the introduction to this chapter, we mentioned the current trend back toward accelerator-produced isotopes. This is occurring partly because of the interest in ultra-short half-life isotopes. Even the nuclide generator falls short of needs if the daughter isotope decays away too rapidly. Also, there are only a limited number of nuclide couplets suitable for such systems. Accelerators are much more versatile.

(a) The diagnostic era, as we know it today, can be said to have developed in earnest from this point, and the credit goes first to Harper (University of Chicago). Bennett (1982) stated that about 90% of routine nuclear medicine procedures now involve $^{99\text{m}}\text{Tc}$.

TABLE 20.6A. Generator Systems*

Daughter Isotope	Half-Life	Parent Isotope	Half-Life	Applications
^{28}Al	2.3 min	^{28}Mg	21.3 hr	Aluminum tracer
^{137}Ba	2.6 min	^{137}Cs	30 years	Dynamic studies
^{68}Ga	68 min	^{68}Ge	280 days	Positron scanning and bone studies
^{132}I	2.3 hr	^{132}Te	3.2 days	Thyroid studies and double tagging
^{140}La	40.2 hr	^{140}Ba	12.8 days	
$^{87\text{m}}\text{Sr}$	2.8 hr	^{87}Y	80 hr	Bone scanning
$^{99\text{m}}\text{Tc}$	6 hr	^{99}Mo	67 hr	Scanning: brain, thyroid, etc.
^{90}Y	64 hr	^{90}Sr	28 years	Therapy

* Commercially available or have been used for special purposes.

TABLE 20.6B. Potential Generator Systems

Daughter Isotope	Half-Life	Parent Isotope	Half-Life
^{72}As	26 hr	^{72}Se	8.4 days
^{131}Cs	9.7 days	^{131}Ba	11.6 days
$^{113\text{m}}\text{In}$	1.7 hr	^{113}Sn	118 days
^{42}K	12.4 hr	^{42}Ar	>3.5 years
^{144}Pr	17.3 min	^{144}Ce	285 days
$^{103\text{m}}\text{Rh}$	57 min	^{103}Pd	17 days
^{44}Sc	3.9 hr	^{44}Ti	~10 ³ years
$^{125\text{m}}\text{Te}$	58 days	^{125}Sb	2.7 years
^{127}Te	9.3 hr	$^{127\text{m}}\text{Te}$	105 days

Source: Modified from Richards 1966a.

In August 1977, the Bureau of Radiological Health of the U.S. Food and Drug Administration (FDA) produced the report of a task force on short-lived radionuclides for medical applications (HEW-FDA 1977). The task force looked hard at many of the known and suspected long-term sequelae of uses of isotopes like ^{131}I and took up the need for larger quantities of short-lived isotopes, already discussed. In an appendix, they list twenty-eight sites where cyclotrons exist capable of producing radionuclides of medical interest. Most of these are in large institutions with support from AEC, the Energy Research and Development Administration (ERDA), DOE, and from the Department of Health, Education, and Welfare (HEW). A few are in industry or smaller academic institutions. Without implying that these machines were not all contributing what they might to the medical sphere, the mere act of listing them undoubtedly brought attention to bear on their potential.^(a)

(a) Some were, as we have seen, already fully devoted to medical uses. Others were only peripherally applied to medicine. In the early years, for example, the Ohio State cyclotron devoted every Monday to producing medical isotopes. However, in the first shipment from the Oak Ridge reactor, they received 350 mc of ^{32}P , more than they could have produced in a whole year. So it is not quantity but quality and short half-life that underlie our interests in accelerator-produced isotopes.

Meanwhile, in Berkeley, a physicist named Alan Fleischer communicated to Bill Myers that he and some others were about to establish a company to build cyclotrons chiefly for medical uses. They were encouraged by Dr. Myers and, as luck would have it, Myers spent part of the first years of his retirement using the first machine built by the company. It was installed some years earlier at the Sloan-Kettering Institute in New York and constituted the beginning of a trend away from complete dependence on government for such devices.^(a) However, the field could never have developed without the strong support of government and collaboration among the medical, basic science, and toxicologic groups.

Laughlin, Tilbury, and Dahl (1971) at Sloan-Kettering Memorial Institute give a useful summary of cyclotrons for medical uses. There may be some difference of opinion on when and where the first fully medical cyclotron appeared. We have remarked several times on the orientation to medical and biological uses surrounding the Berkeley machines in the early Radiation Laboratory and the Crocker Laboratory, but these machines did many other things; ditto for the machine at MIT. We can be assured that potential biomedical uses, particularly in cancer research, were prominently displayed in the funding proposals for nearly all of the machines listed in the HEW-FDA report cited above. It is commonly stated that the first cyclotron built entirely for medical uses was at the Hammersmith Hospital in the United Kingdom under the stimulus of L. H. Gray. Since this machine was in a hospital and not part of a general university facility, it may well warrant the title. In the United States, machines of similar purposes and characteristics appeared at Washington University in St. Louis and elsewhere (Laughlin, Tilbury, and Dahl 1971).

Myers, the consistent visionary, believes nearly all large hospitals will someday have small cyclotrons to make his "twinkling" atoms (Myers 1981b). The cost of such machines is being drastically reduced but is still substantial, even in modern-day medicine. When chided by some less enthusiastic surgical colleagues, Myers retorts with, "How much did your operating room cost?" (Myers 1981a).

There seems little doubt but the availability of radioactive isotopes with very short half-lives and suitable energies for scanning makes predictions for still more growth quite reasonable. At the Dallas meeting of the Society for Nuclear Medicine in 1976, there were over two hundred papers using cyclotron-produced isotopes. The idea had obviously grown and spread.

4. Instrumentation and Methodology

We have called this period the "Era of Ever More Scanning and Ever Shorter Half-Lives." The dependence on new sources of isotopes *in situ* is now obvious. In this section, we will look very briefly at the measurement and recording side. Not described to any extent in this chapter, but seen earlier (chapter 17), were the basic instrument and methodologic developments. Started in the major national laboratories, even the MED, the development gradually shifted to private industry during these years. Many manufacturers produced instruments for health physics, tracer chemistry, and nuclear medicine as part of diversified

(a) It was hardly a complete change from dependence on government, only a change of *modus operandi*. Bennett (1981) stated that the United States paid for the machine.

operations. Others began to specialize. The instrumentation for the era we are now in has become not only very complex but very specialized.

The generic term "scanning" (or "imaging") was applied to these devices and processes. The early approach was to place a Geiger counter over the area to be measured as in the now-classic picture reproduced as figure 20.6. This gave no spatial orientation except by hand movement of the counter. It gave essentially a count rate or an integral count over a selected period.

As interest developed in counting organs besides the thyroid, many of them much larger, the labor of moving the counter by hand—and the inaccuracies involved—led to the development of mechanical scanners. These could be programmed to cover a series of coordinates and, thus, were "rectilinear scanners."

The first successful rectilinear scanner was developed by Benedict Cassen in 1951 working at UCLA (Cassen et al. 1951). It was very useful as was its successor designs. Indeed, it made enough difference to the practice of nuclear medicine that the original is now in the Smithsonian Institution. Yet they had their limitations.

An entirely different device, first described under the simple title "Scintillation Camera," was introduced by Hal Anger at the University of California at Berkeley (Anger 1958). This device could view the entire field without moving, but the field was somewhat limited, and for a while the mechanical scanner had greater sensitivity. However, developments came rapidly. Anger, who was described by Wagner (1981) on the occasion of an award as "a convergence of nuclear physics, electronics, optics and information handling," described the scintillation camera at the second Atoms for Peace Conference in Geneva, Switzerland (Anger 1959), and improvements came in rapid succession (Myers 1979).

A device developed at The Ohio State University and called the "Gammicon" was something of a hybrid. It used a scintillation detector and a calcium tungstate crystal (not sodium iodide as in the later devices), but for the scans it utilized the Teledeltos system devised by the Western Union Company to transmit pictures by wire (Mueller and Myers 1955).

Obviously, a large advantage of the scintillation camera is the ability to present dynamic states such as blood flow, dye movement, and related measurements.

The steps in development of these and other devices is nicely summarized in the Nuclear Medicine Pioneer Citation-1974 for Hal Oscar Anger, D.Sc. (Hon.) in the *Journal of Nuclear Medicine* for June 1974 (Myers 1974a). The early (1952) gamma-ray camera had a 3-mm pinhole in a lead shield and needed concentrations of ^{131}I of about a millicurie per square-centimeter area for reliable detection. The much more sensitive version of the scintillation camera came about five years later. By 1963, an 11.5-in. crystal was employed. Much is said about the matching of isotope with camera. Anger also developed the multiplane tomographic gamma-ray scanner and a whole-body scanner. No single individual seems to have invented and developed so many measuring devices for nuclear medicine; and it was all done from one of AEC's most consistently supported laboratories.

It took a few years for commercial developers to decide these devices had a future. There was also a considerable period during which there was debate as to the relative merits of camera versus mechanical scanners. Also, there were problems about patents and much red tape. Further detail is beyond our scope, except to mention that the present instrumentation embodies the best features of all systems, including computerized operation and printout or display. The

debate now seems (in the mid 1980s) to be around digital versus analogue systems, a long step from the early Geiger tubes.

In 1979, the Office of Health and Environmental Research of DOE reported the work of a study group appointed to examine nuclear medicine instrumentation development (DOE 1979). This added to a report in 1976 from an ERDA/NIH task force. It commented on the importance of continued instrumentation development to both biomedical research and the diagnosis of disease. It recommended substantially increased support for instrumentation research and development and a stable, long-term commitment of support for established research groups. It also urged effective means of technology transfer among the basic and applied physics, chemistry, and engineering programs and with NIH programs. The task group did not concur with the view that nuclear medicine may have reached the stage where innovation and product improvement could be expected entirely from the commercial sector. Thus, a continuing role of government in this enterprise, which could never have gotten started without government support, is urged by this blue-ribbon panel. Particular emphasis was placed on assurance of technical feasibility and clinical efficacy before undertaking commercial development. Undoubtedly, this view does not prevail at present, but the arguments are well worth examining.

Finally, the role of the synthetic chemist should not be forgotten. An important part of the methodologies of this second era is the development of ever more specific compounds to help direct the new short half-life isotopes to desired areas or for desired functional measurements. While not quite up to the specificity we can expect in an antibody system, many radioactive pharmaceuticals are significantly advanced. However, these considerations are getting us too far afield to warrant description, except to say that many of the ideas started in the institutions we have become familiar with.^(a)

C. A Possible Third Era

Despite the many discouragements toward finding broad applications for the therapeutic uses of radioisotopes, the research did not halt altogether. Ideas kept springing up that showed promise enough to be funded by the NIH or in part (especially earlier) by AEC, ERDA, and DOE. At least two are directly related to approaches and people we have already described. A third, therapy with beams of particles from facilities like the Meson facility at Los Alamos, is really not a radioisotope technique. Even though these beams contain particles of high-LET and are thus related to much of our discussion of alpha emitters, we must leave their discussion for others.

The first extension to consider is that developed by Bill (Dr. William F.) Bale (see section IV A 7). We look at it first because, unfortunately, it is now completed, except for publication of work in progress. Dr. Bale, a long and dear friend to this author, died in Atlanta in mid-1982.

There was a powerful source of ^{90}Sr at the Georgia Tech Medical Research Foundation where Bale went after his retirement from Rochester. He and his colleagues (especially Angela de los Angeles Contreras) could milk this source

(a) The money has come in recent years from very diverse sources. For example, it is said that investment funds for the so-called "CAT Scanner" came from the singing group, the Beatles!

for the decay product, ^{90}Y . This could be adsorbed onto ion exchange resin microspheres, separated, and incinerated to become carbon microspheres about $15\ \mu$ in diameter.^(a) This size would lodge in capillaries of an organ like liver into which they could be placed by the surgeon (an Atlanta surgeon named Grady did much of this work) using a catheter in the hepatic artery. By chance, the liver tumors of interest get most of their circulation from the hepatic artery, even though the whole organ gets about two-thirds of its blood from the portal vein. The combination of anatomical localization of the microspheres and the hard beta ray of ^{90}Y conferred many potential advantages.

Along with this work with microspheres, Bale expanded his earlier work with antibodies as carriers of radioactivity. Again we must give the work short shrift here, except to indicate that it may be ready for a new sprint of activity somewhere using monoclonal antibodies, which have localization potential even greater than the conventional antibodies used in work such as that done by Bale and his group (Cronkite 1982; Sutherland 1988).

The second potential development that may usher in a new era of therapeutic interest is located primarily at Brookhaven and in Japan, with some work at other installations including Georgia Tech. This may eventually hinge on coalescence of several of the approaches worked out earlier.

Even though neutron-capture therapy seemed dead in 1961, by 1966 it was revived by development and use of an epithermal (i.e., above thermal) neutron beam rather than the thermal beam used in the original Brookhaven and MIT work. One of the problems with thermal beams is their rapid (and exponential) attenuation in tissue and the consequent high dose to surface tissues. Fairchild and Goodman (1966) at Brookhaven and Columbia University determined that tumors deeper than 2.5 cm could not be treated with a thermal beam, even with the best attainable localization of ^{10}B in the tumor. Potential advantages of factors up to 1.9 could be predicted at all depths greater than 1.5 cm with the epithermal beam from the Brookhaven Medical Research Reactor. Work with phantoms was helpful but not really exciting without better localization of the boron or some other neutron-capturing element.

In the intervening years, much was done to improve the dose localization possible with epithermal neutron beams from reactors like, but not limited to, the one at Brookhaven. Also, the development of much better carriers to localize the boron received much attention and encouraging development (Fairchild 1982a). At the International Symposium on the Synthesis and Applications of Isotopically Labeled Compounds held in Kansas City, Missouri, in June 1982, Fairchild (1982b) considered the dosimetric implications for beams of epithermal neutrons of a sulfhydryl boron hydride and of borated analogues of chlorpromazine, thiouracil, porphyrins, amino acids, and nucleosides. Only the first has been used clinically: $\text{Na}_2\text{B}_{12}\text{H}_{11}\text{SH}$,^(b) and it has been used primarily in Japan by Dr. H. Hatanaka.

(a) The microspheres were originally prepared by the 3M Company (Grotenhuis 1966; see section IV A 7), but the labor of being certain absolutely no ^{90}Sr contaminated the ^{90}Y ran the cost and problems up so much that the Atlanta group decided to do the preparations themselves (Bale 1979).

(b) It is called a "second generation" compound of boron by investigators. Earlier water-soluble pentaborates used by Farr, Sweet, et al. were considered "first generation."

The Japanese work has been going on since 1968 and has concentrated on glioma (brain tumor) patients. It is a fairly heroic treatment since craniotomy (removal of a section of the skull) and surgical removal of all accessible tumor tissue were routine, followed by radio- and chemotherapy and neutron activation therapy. The craniotomy provided much more favorable depth-dose conditions for the epithermal neutron beam than would otherwise have been the case. The combination therapy (i.e., sulfhydryl boron hydride and epithermal neutron beam following conventional surgery and other therapy) has now been tried on fifty-three patients (Fairchild 1982a). There have been some "cures" lasting eight to nine years, a very significant increase for the usually rapidly fatal glioblastoma. A summary of twelve years of experience in Japan has been provided by Hatanaka et al. (1982).

The quest for other compounds that would carry the boron or other elements with high neutron capture cross sections has not reached the point of clinical application, in the United States at least. The compounds described by Fairchild might be considered "third generation" boron-carrying compounds. So far, the enhancement of dose from epithermal neutrons has been confined to work with phantoms. Procedures for borating antibodies have been developed and as many as two thousand boron atoms placed on each antibody molecule. (Remember that Bale and Spar's calculations indicated twenty-seven ^{10}B atoms should be enough.) However, specificity and adequacy for neutron capture therapy remain to be demonstrated. Enthusiasm is high, particularly for monoclonal antibodies (Cronkite 1982; Fairchild 1982a; Sutherland 1988). It would indeed be important if a combination of the techniques that have alone produced marginal results produced a significant therapeutic advance.

Other ideas should be mentioned. One harks back to getting a labeled compound more specifically to a tumor. The Brookhaven group (Fairchild et al. 1982) have found that thiouracil gets incorporated into the biosynthetic pathway of melanin as a false precursor and remains bound. Absolute uptake of labeled thiouracil by mouse melanoma was relatively high. Tagging with ^{35}S is contemplated since such a compound is available commercially. This *might* be almost as specific as iodine in the thyroid.

Another is the use of the spontaneously fissionable ^{252}Cf . The potentials for this radionuclide were described with enthusiasm by Seaborg in 1973, as part of a general compendium on possible medical uses of transuranium elements (Seaborg 1973). The fission produces an enormous local dose. Localization of ^{252}Cf to tumor sites has not been an easy task.

Another new idea harks back to the advantages of ^{125}I . Here the ^{125}I is made in situ by introducing into DNA a thymidine analog (deoxyuridine was best) that had been labeled with stable iodine (^{127}I). The bound iodine was then photoactivated with 33- to 60-keV monoenergetic photons. This produces ^{125}I with all its advantageous Auger electrons, etc., in a very localized manner and avoids the presence of ^{125}I radiations in other areas. Obviously, the idea is comparable to neutron activation but employs photoactivation. The Brookhaven group is especially enthusiastic about this approach (Fairchild, Brill, and Ettinger 1982).

Only the future can tell whether or not these ideas, which seem very promising, will spark a recrudescence of interest in new therapeutic applications of radioisotopes. They seem sufficiently promising, and sufficiently adherent to the maxim of reducing the unwanted radiation dose to normal tissues, to warrant attention here. It is unlikely that this third era, if it does develop, will see any decrease in the diagnostic uses of radioisotopes in nuclear medicine. At most,

it would mean a possible broadening of the therapeutic uses with no letup in the scanning, development of short half-life isotopes, and of ever better instrumentation.^(a)

I have chosen developments from selected laboratories close to the radioisotope toxicology enterprise. There are, of course, many others. However, the examples should show how the contributions from former AEC, ERDA, and currently DOE and PHS laboratories have continued to advance nuclear medicine despite retrenchment of support. Fortunately, support from agencies such as the NIH has stepped in for some of the most interesting and promising developments. It is a lively and fascinating field.

V. Summary and Commentary

Quite obviously, we cannot hope to present a detailed history of nuclear medicine and tracer chemistry in a volume that, like this one, is devoted to other areas. Yet, the research and the investigators concerned with health effects of radioactive materials have been, and always will be, closely related to both nuclear medicine and tracer chemistry. In fact, they have common roots, as was detailed in chapter 5. Frequently, two or more aspects can be found in the same individual. To further delineate these interrelationships, the chapter begins with a mock genealogy. This includes the locales that could be regarded as the "old homestead" for the family of disciplines.

For the first time in this long book, a formal discussion of dosage calculations is introduced. This is commonly referred to as "internal dosimetry" since it concerns radiation doses from internally deposited radionuclides. The delay in introducing dosimetry was so that the MIRD system, developed primarily for nuclear medicine and by practitioners of nuclear medicine, could be discussed side-by-side with the classical system usually attributed to Marinelli, Quimby, and Hine, with important later contributions by Snyder. Only a few detailed illustrations are given since other sources expound internal dosimetry in depth. Yet, it is hoped they provide the reader with a grasp of the concepts and the types of information needed.

Even in the 1930s, medical uses of radioisotopes, for both diagnosis and therapy, were undertaken. The relatively limited supply of radioisotopes, their short half-life, and problems of purification confined these early efforts to large installations handy to an accelerator. During World War II, the medical-use effort was severely truncated, partly by lack of supplies and partly by occupation of the same personnel with the new potential health problems of the nuclear age detailed in this book. Soon after the close of the war, particularly under the stimulus of the Atoms for Peace Program, supplies of radioisotopes became almost unlimited, and nuclear medicine began its meteoric rise that still continues. Tracer chemistry required relatively less material and seemed to grow even during the war years because of the tremendous power of the technique.

The effects of radiation and radioactivity at the cellular level and their mechanisms constitute a major portion of the field of radiobiology. The applications to nuclear medicine and the perfection of tracer techniques added measurably

(a) That there has been no letup is demonstrated by the very recent book by Bragg, Rubin, and Youker (1985) under the title *Oncologic Imaging*. The subtitle states, "Oncologic imaging is saving lives." Also, the monoclonal antibody has stimulated full-scale international meetings (Sutherland 1988).

to knowledge of cell effects gained from other sources. The chapter reviews some of the highlights of these.

Specific applications of radionuclides in medical practice can be discussed conveniently in two basically different contexts—diagnosis and therapy. The earliest work considered diagnostic tests but was soon followed by attempts at therapeutic uses. In the decades of the late 1940s through the middle 1960s, the hopes for making order-of-magnitude advances in cancer therapy guided much of the work. Diagnosis was not neglected, but the spotlight was on therapy. Manipulations of carriers were legion. All of them had the purpose of increasing the relative dose to tumor tissue and reducing that to normal tissue. These manipulations included use of radiocolloids, microspheres, attaching the radioactive material to specific antibodies, *in situ* neutron capture techniques, and others. Naturally, new isotopes with more desirable properties were tried also. However, the results did not live up to expectations. The age-old problem of specificity, *i.e.*, killing the target cells with minimal effects on normal cells, brought disappointment after disappointment. Now, a few standard therapeutic modalities are commonly used as a result of all of these efforts, but only a few.

As techniques for measurement of radioactivity and for scanning specific anatomical areas, either statically or dynamically, advanced, so did the uses of radionuclides for diagnostic tests. Pharmaceuticals were developed that had great specificity for localizing in areas of interest. Also, shorter half-life radioisotopes appeared in pure form that could be incorporated into the radiopharmaceuticals and greatly reduce the dose to the patient. Thus, the period from the mid-1960s to the present is dubbed, herein, an era of ever more scanning and ever shorter half-lives.

Toward the end of the chapter, some current advances are described that may produce a revival of interest in uses of radionuclides for therapy.

The constant role of potential unwanted health effects has perforce been emphasized in the chapter. There can be no doubt but the health benefits of the uses of radioisotopes under the aegis of practitioners of nuclear medicine have been enormous and far outweigh any demonstrable untoward side effects. This is particularly true for the diagnostic uses. It is incontrovertibly true for the researches aided by tracer techniques. Nevertheless, the workers in the field of diagnostics and their compatriots concerned with possible toxicologic effects have had to be guided in all of their developments by balancing effectiveness and delivery of the lowest possible dose to the patient. In therapy, the dictum has been likewise the production of the minimum unwanted dose to normal tissue while delivering an effective dose to the target cells. These two considerations have put many a technique on the shelf. The duality attests, as stated at the outset of the chapter, to the close relation between the major branches of the family of workers concerned with the biomedical aspects of radionuclides.

Chapter 21

Concluding Comments

I. Highlights

Many thousands of lives have been saved or made more comfortable by the uses of radioactive materials in medicine. This ranges from the early uses of the gamma rays from radium in encapsulated sources for the treatment of cancer and the insertion of radon seeds directly into areas suitable for such treatment, through the uses of radioisotopes of iodine, phosphorus, gold, and others for diagnosis or therapy, to the current enormous utilization of radioisotopes in nuclear medicine. (It is estimated that approximately one quarter of all hospital admissions now involve a nuclear medicine procedure at some stage.) This positive effect far exceeds the number of untoward effects of the uses of radiation and radioisotopes. If we add to this the tremendous advances in the understanding of biological processes at all levels, from molecular to the whole organism, made possible by the uses of radioactive materials as tracers, the balance becomes still more one-sided.^(a) Yet there has always been concern for proper control of the uses of radioactivity in industry and in medicine. This has ranged from rudimentary in the early days to stringent controls at present. While the accomplishments of nuclear medicine and of tracer chemistry have received ample attention and review over the years, the work and ideas of the cadre of scientists devoted largely to understanding all levels of effect and behavior of radionuclides from the apparently harmless to the obviously deleterious has not been systematically reviewed. The purpose of this book is such a review, with emphasis on work done in the United States.

Clearly we have learned much, but clearly there is much left to be learned. In this first section of the concluding chapter we will list some of the highlights of what we have learned. In a later section, we will list some of the problems for the future.

(a) See, for example, Hearings on Applications of Radioisotopes and Radiation in the Life Sciences (U.S. Congress 1961). This early version required four days. Now thousands of experiments are based on radioisotope techniques.

A. What Have We Learned About Effects?

It is clear that *qualitatively* the effects of ionizing radiation from deposited radionuclides are comparable to those from external radiation sources. It is equally clear that there are quantitative differences. Many of these reside in the fact that radioisotopes are seldom distributed uniformly in body tissues. There are nearly always tissues or organs with concentrations well above the average. More effect is seen with these to a degree dependent on the energy and range of the emitted radiations as well as concentration. In many cases, effects, especially long-term effects, may be almost entirely confined to a single tissue or organ, such as bone or thyroid. These properties underlie most of the attempts to use radionuclides in therapy. They also lead to instances where effects appear in a system that never would have shown itself under most conditions of external radiation.

There are large differences in the effectiveness of different deposited radionuclides, even in the same tissue. These go well beyond any differences in absorbed dose, even beyond differences due to different linear-energy transfer (LET) rates noted with external radiation. They reside in differences in the microlocalization of the atoms with reference to the most sensitive or target cells. The phenomenon was earliest and best illustrated by differences between those bone-seeking elements that exchange for calcium (e.g., radium and strontium) and thus distribute eventually throughout the volume of bone and those that deposit primarily on surfaces within bone (e.g., plutonium, the transplutonic elements, many of the rare-earth-type elements). Because of the practical importance of these phenomena for standard-setting, and their inherent scientific interest, many extensive experiments were performed. Some of these are among the longest biomedical experiments ever brought to fruition because of the very long latent period involved in the production of the effects of most concern.

There are persistent differences among animal species in the mix and quantitative aspects of both short- and long-term effects. These differences stimulated the introduction of new species and new strains and attempts to explain the phenomena noted. In some cases, the phenomena have been explainable, in other cases not. Sometimes new species or strains have shown more consistent behavior than was earlier revealed. The phenomena sometimes support the statement that "the proper subject for the study of man is man" (Evans 1983), and emphasize the need to extract all possible information from the ongoing studies on man. Nevertheless, there is much needed information that can be obtained only by experiments that could not possibly be done with man as the subject. Thus, best-guess extrapolations to man have been consistently needed and have required much effort.

The new dimensions brought upon the biomedical world by the production of the fission products in large quantity and the *de novo* presence of plutonium and related actinides led to advances in our knowledge that would never have occurred otherwise, at least not in so short a time frame. The concentrated attacks on these made during the war years under the aegis of the Manhattan Engineer District (MED) have stood the test of time and formed the basis for much additional work.

A similar large effort surrounded natural uranium, although it was not quite a "new dimension." Chemical toxicity to the kidney, the most likely acute effect, vies with potential long-term radiation effects as a basis for exposure standards to uranium.

The primary expected route of entry into the body of radionuclides released in the workplace is inhalation. A large amount of experimental work has concentrated on the inhalation route. Indeed, one major installation has been devoted almost entirely to inhalation experiments. It has turned out that deposits of insoluble forms of radionuclides in the lungs can be a potent source of lung cancer, sometimes exceeding the potential for bone cancer. In addition, much has been learned about respiratory physiology and pathology in the course of this work.

The role of radon daughter products in the production of lung cancer in uranium and other hard-rock miners has been proven beyond doubt. The saga of the miners covers by far the longest period of investigation depicted in this book. The results of studies of animals and of man indicate a possible species difference in the site of origin of the lung cancer and thus in the mechanism. The role of adjuvants has been especially thoroughly investigated in this work, but the answers are equivocal. Natural radon in homes is an important new dimension.

Throughout the work on inhalation effects, it has been necessary to construct reliable systems for the controlled production of radioactive aerosols. These techniques and installations have been unique and led the way for all of inhalation toxicology.

The potential for effects of radionuclides released to the environment from nuclear installations was one basis for development of an entirely new field, radioecology.

The new dimension of fallout from nuclear weapons testing led to much work on the possible effects of low doses of deposited radionuclides in humans, animals, and in ecosystems, as well as on the movement of radionuclides in environmental media.

Dosage calculations associated with effects of deposited radionuclides follow two major systems, the classical system usually attributed to Marinelli, Quimby, and Hine and a system developed by the Medical Internal Radiation Dose (MIRD) Committee of the Society of Nuclear Medicine. The basic principles of both systems are given in the text, but many of the complexities have been omitted. This was done, in part, because the dosimetric systems have, in this author's view, become complex far beyond the precision needed for biomedical work. Nevertheless, even with the most complex formulations, it is not possible to answer *simply* whether or not a given absorbed dose of radiation from a deposited radionuclide has the same effect, quantitatively, as the same absorbed dose from an external source. There are instances where there appears to be a significant difference. Attempts are still being made to attribute some of these to a chemical effect of the element concerned, but they have not been notably successful, except for natural uranium.

Very low-energy beta emitters may produce more or less specific effects within cells in which they are localized. Radioisotopes that produce Auger electrons likewise appear to have unique properties vis-à-vis the effects they produce.

On the whole, radionuclides do not deposit selectively in gonadal tissue and unique mutational events from this source are not common. The risk from genetic effects thus is, in general, comparable to the same dose from an external source. However, the amount of work done in this field is small relative to the needs.

The possibility of a transmutation effect (when a radionuclide that is incorporated in a vital macromolecule decays and thus becomes a new element) has

received much attention. On balance, it appears that bona fide transmutation effects occur only under rather special circumstances. They contribute little to the overall effects of deposited radionuclides.

The dose-response curves for the effects of deposited radionuclides are frequently complex. Their shape is seldom simple linearity but rather a linear component followed by a dose-squared or other components with indications of other shapes, including ones consistent with the idea of a "practical threshold." This is discussed especially in connection with the bone-seeking radionuclides. It appears that the assumption of linearity for purposes of standard-setting must be considered a rather gross simplification in many cases.

Dose fractionation experiments did not provide answers identical to those expected from experience with external sources. While some experiments with beta and beta-gamma emitters indicated lesser effects with protracted or fractionated doses, others, particularly with alpha emitters, appeared to show greater effectiveness of protracted doses. Since the radionuclide is sometimes present for long periods, the situation is rather different from that with an external source that can be turned off completely.

Much effort around the "hot particle" problem failed to demonstrate, in general, any greater or any special effect of exposures to these intense sources.

During World War II, and in the immediate postwar years, interests centered on the acute effects of moderate to high doses of radiation from either external or internal sources, and this occurred despite the accumulating information on long-term effects in the radium dial painters and patients (chapter 1). By contrast, in the post-World-War-II era, much emphasis was placed upon formal study of the longer-term effects of radiation. Both external sources and deposited radionuclides were involved. Beginning with longer observation periods on animals receiving moderate, even high doses, the work extended gradually to lower and lower administered doses and body burdens. In the late 1940s and early 1950s, rodent colonies contributed most of the information. Later the large life-span beagle studies confirmed and expanded the picture (chapters 8 and 13). Because of the interest in using the relative carcinogenic potential of several bone-seeking elements for development of exposure standards using radium as the bench mark (chapter 16), much emphasis was placed on plutonium, americium, other actinides, and strontium. There were also long-term experiments on radioiodine, particularly involving rodents and miniature swine (chapter 8).

Much was learned about the carcinogenic potential and general effects of these and related elements on many physiological systems. These are detailed at appropriate places throughout the text, and are summarized in the paragraphs above.

We still need more information, especially at very low doses, but in toto we have gained, by orders of magnitude, in our comprehension of the long-term effects of deposited radionuclides. In fact, more is probably known about these than about the majority of chemically toxic entities in the work place or the environment.

B. Metabolism (Pharmacokinetics)

It was necessary to determine the behavior in various living systems of any and all radioactive materials under study. While in general their behavior might be predictable from the chemistry of the element involved, the quantitative aspects were frequently not well enough established and had to be fleshed

out by work with radioisotopes. There were some unexpected differences from predictions.

As expected, chemical form played an important role in lung or gut uptake, as well as in subsequent distribution to tissues. For inhalation exposures, the particle size and its distribution were added factors and of considerable importance. It soon became apparent that many radionuclides formed complexes of varying degrees of stability with ligands in blood and/or tissues. In the earlier studies, complexing was especially well worked out for uranium. Also, complexes and methods for induction of complexing undergirded much of the work aimed at therapeutic removal of deposited radionuclides.

It was also apparent that colloidal states existed in many instances; in both injection solutions and in vivo. This led to uptake by, and the usual reactions of, the reticuloendothelial system (RES) to particles of colloidal size. Deposit and retention in tissues such as liver, spleen, and bone marrow frequently followed. By contrast, the same substances entering via absorption from the gastrointestinal tract or, to a lesser degree from the lung, were less likely to be in colloidal form and thus go to the RES in lesser quantity. Differences in distribution and excretion followed these different routes of entry.

The retention of radionuclides in tissues was subject to intensive kinetic analysis. This was needed partly to serve the needs of dosage calculations and partly for its intrinsic interest. Normal physiological concepts predict first-order kinetics of loss from each of one or more compartments. Many retention data could be fitted by exponential functions of time, most frequently by two or several, rather than by one exponential, indicating more than one compartment of retention. Frequently, however, particularly for long-lived, long-retained radionuclides, the data were fitted best by a power function of time. This may represent only the summation of many exponentials, but has impressed many investigators enough to be advocated as a formulation for practical use.

Each group of radionuclides has, of course, its own pharmacokinetic pattern, modified by the presence or absence and nature of complexers. Unexpected was the finding that different isotopes of the same element could exhibit different metabolic patterns (e.g., ^{238}Pu differs from ^{239}Pu , the iodine isotopes differ from each other). Differences in specific activity may underlie some of these phenomena with, for example, higher-specific-activity materials causing radiation-based destruction of complexes or of imbibing cells. The net result is a need for actual study of each isotope of interest. Projections on a generic basis are not enough. A start has been made on such experiments, but only a start.

The behavior of inhaled radionuclides was likewise not accurately predictable. There appears to be no substitute for an actual inhalation exposure experiment. Even intratracheal instillation is not the same.

Judicious tracer-level experiments in humans indicated reasonably satisfactory agreement between the metabolic data obtained from animals and those found in man. Some of the noted differences can be explained on the basis of anatomy (e.g., the relative amounts of cortical and trabecular bone) and thus reconciled. There were occasionally wide differences in excretion rates among animal species and between some animal species and man that require consideration for bioassay procedures. Only a few of these differences have been explained.

Experience around nuclear sites and with fallout from weapons tests provided much information on the movement of radionuclides in the biosphere. Conversely, the presence of radionuclides helped to describe major movements in

components of the environment, such as the atmosphere and the hydrosphere. The fact that many organisms can act as sinks for radioactivity and thus contribute to gradual increases in tissue concentrations as one progresses up the trophic chain was amply demonstrated. Differences in the movement of radionuclides in different environments and in different organisms led to the concept of critical pathway and its corollary, the critical population, in the setting of population exposure standards. Now the accumulated information supports extensive computer models for environmental transfer. Correlates of the information on environmental transfer extended to the development of environmental impact statements and have been important in undertakings such as Project Plowshare.

Information gained from some of the environmental experiments led to cancellation of planned projects.

Some broad features of many of the ocean currents and of atmospheric circulation patterns, including the jet stream, have been developed, in part, using data for radioisotope transfer developed from the measurements of fallout from weapons tests.

Biological entities play an important role in some of the environmental transfer systems, a relatively minor role in others.

C. Applications

In addition to the intrinsic interest in finding out about the metabolism and effects of both natural and manmade radioisotopes, there were many practical needs served by the research efforts described in this book.

A consistent focus of the investigations has always been the development of realistic standards for limiting intake of radionuclides. The research data have been enormously useful for this, indeed essential. The applications have been in two forms:

1. *Direct use of observed effects as a function of dose or body burden.* The classic example is the standard for ^{226}Ra that was developed entirely by the finding of levels in humans that were or were not associated with observable biological effects. This standard, developed in 1940 and published in 1941, has remained valid ever since, confirmed and strengthened by additional information. An exposure standard for radon was developed at the same time based upon measurements, industrial hygiene style, of air concentrations in the work environment, correlated with evidence of effects in humans. A third example is the standard for uranium, which was derived largely from data obtained in animal experiments since effects in man were marginal or not observed.

Direct derivation in humans of a standard for plutonium was not possible, thankfully, for the same reason, lack of significant numbers of clearly affected individuals. However, the standard for it was based upon the radium standard and was thus quasi-direct. To do this, the relative effectiveness of plutonium and radium was determined in several large animal experiments and the ratio of allowable body burdens equated to the ratio of effectiveness. As new data accumulate, we can expect further attempts to calculate risk to humans for other radionuclides directly from the data on effects:

2. *The indirect or computational approach.* When it was decided to set standards for the many hundreds of radionuclides developed in the years of the MED, a different approach was needed, since sufficient data for a direct approach existed for only a few. To accomplish this, the limits were set by

computation of the radiation dose rate to the target organ (critical organ) or whole body, and intake was limited so that the delivered dose would never exceed that allowed the same organ or tissue from external radiation sources such as x or gamma rays. This required knowledge of gastrointestinal-tract absorption, behavior in the respiratory tract, distribution to the various tissues and organs, retention therein, and the kinetics of excretion. All of the research data gathered on humans and animals concerning pharmacokinetics (metabolism) were screened for this purpose. Best estimates were made for the parameters needed for the computations. In some cases, the amount of information was insufficient, and decisions had to be made by reference to analogues. Also, because the quantities involved with many radionuclides were exceedingly small (by weight), it was desirable to know the amounts of many trace elements already present in the tissues of humans. Thus, the "pool" size into which the radioactive isotope would be diluted could be determined. A special project was operated to determine these trace element quantities in humans.

The computational approach has now reached enormous proportions. Beginning with the 1959 reports of the U.S. National Council on Radiation Protection and Measurements (NCRP) and of the International Commission on Radiological Protection (ICRP) and the subsequent compilations by the Atomic Energy Commission (AEC) and the Nuclear Regulatory Commission (NRC) into Federal Regulations and many other intermediate stages, we see a culmination (for the present at least) in the enormous volumes from the ICRP published in the recent past (cited in chapter 16). These give physical and biological data and the calculated annual limits on intake and derived air concentrations for over seven hundred radionuclides. The bulk of the data used is on file, and the computations were made at the Internal Dosimetry facility of Oak Ridge National Laboratory. Revisions and expansions to population exposures are now in preparation. These and all other documents, past and future, depend entirely upon the research data generated in the projects described in this book.

The research data have also been brought to bear on the validation of standards already extant. Several epidemiologic investigations are described that have particular significance for this purpose. As new epidemiologic work grows and current projects come to completion, we can expect a considerable expansion in this validation process.

The research data have been used for developing specialized models such as those for behavior of radionuclides in the respiratory tract and in the gastrointestinal tract, the behavior of alkaline earth elements in bone, and others.

An additional need was to define average anatomical, physiological, and biochemical parameters of humans for use in computations or model making. As a result, collaborative work between investigators in the radionuclide field and conventional anatomists, physiologists, and biochemists led to development of a "standard man," now called "Reference Man."

The fields we now know as nuclear medicine and as tracer chemistry had a common origin among investigators interested in the applications and use of radionuclides. While each now has its own identity, the research described in this book contributed significantly to each and vice versa. This is reviewed primarily in chapters 5 and 20.

The attempts to develop therapeutic means for removal of deposited radionuclides rested squarely upon applications of the knowledge about their behavior already gained. Conversely, the special studies of therapy added new information concerning the behavior of radionuclides in living organisms. This

included the finding that fixation could occur quite rapidly, and early institution of therapy was frequently essential.

Many applications of the research described in this book are more or less indirect, indeed, symbiotic. Among these would be the developments in therapy with radioisotopes and diagnostic procedures used in nuclear medicine (chapter 20); development and use of environmental transfer functions; the basic inputs for environmental impact statements and the like (chapters 11 and 15).

An example of an even more indirect application can be seen in the development of new strains of salmon and trout through the University of Washington program. This development was technically almost separate from the radiobiology program and of much longer standing, but it was clearly advanced by the presence of the financial support and activities that spilled over from it. Hines (1976), in a charming and comprehensive book entitled *Fish of Rare Breeding—Salmon and Trout of the Donaldson Strains*, describes the fisheries program that began in the 1930s and is still active. It was primarily a genetic selection program, but eventually became a "farm" operation. It is safe to say that productivity of Pacific species was notably enhanced, and also strains developed that have played a major role in the repopulation of some, if not all, of the Great Lakes and other bodies of fresh water. To a degree, the radiation program piggybacked, intellectually at least, on this long-standing effort. Yet, there was clearly more work possible because of the program built around understanding possible effects of effluents from the Hanford reactors.

A picture of Dr. Donaldson with one of his "pets" is shown as figure 21.1.

FIGURE 21.1. Dr. Lauren Donaldson with one of his "pets" at the University of Washington. (From Hines 1976.)

II. Correlates to Mechanisms

A. The Setting

On several occasions in the description of the research efforts, it was noted that the investigators took every reasonable opportunity to seek mechanistic explanations for the phenomena observed. In the early years, biomedical science was not far enough advanced for any review of the mechanisms proposed to have

current meaning. Therefore, these have been omitted for the most part. During the years of the MED, the generation of empirical data on behavior and effects had to take precedence. Mechanisms were guessed at and some work done, but serious investigations into them had to be postponed. After the pressures of the war years were over, more time and resources could be and were devoted to seeking explanations for the phenomena observed. Some of these have been noted along with the descriptions of the findings; for example, the basis for discrimination factors between pairs of isotopes (chapter 13), the likely explanations for some of the transfer and concentration factors in the environment (chapter 15). In other cases, independent studies were mounted to go further into mechanisms. These are not reviewed in any detail in the individual chapters. A few are summarized very briefly herein. In still other cases, it can be said that a whole new field grew from the initial forays into mechanisms. An example of this will be given in this section.

In a sense, this section might be labeled "spin-offs to basic science." However, this appellation implies a qualitative difference in objectives that is not appropriate to the field of this review. If we define "basic science" as science done with absolutely no thought of the reasons for doing it, then none of the work we have been or are discussing could be called basic science. All of it had fairly specific objectives. A more suitable discrimination is between mechanistic and descriptive considerations.

B. Cellular-Level Correlates to Mechanisms

There are many possible examples. We will emphasize only a few.^(a)

1. Uranium and Cell Surface Enzymes

In chapter 2, we noted that the attempts in the work at Rochester to understand the mechanisms of uranium poisoning uncovered the presence of enzymatic poisoning in and on the cell surface. This essentially developed into the field of membrane biophysics as we know it today. The principal investigator involved was Dr. Aser Rothstein, now Director of the Research Institute at the Hospital for Sick Children in Toronto, Canada. Let us review the development in Dr. Rothstein's own words (Rothstein 1983), somewhat more circumspect than the broad generalization made above:

If you remember, after the war-pressure was lifted, I started to explore the effect of uranyl ion on sugar transport in yeast, stimulated by my Ph.D. thesis on membrane function in that cell, and by the known effect of uranyl on sugar reabsorption in the kidney. It turned out that uranyl was an excellent probe for transport systems because it didn't penetrate and because it interacted chemically with finite, chemically definable, functionally important populations of binding sites on the surface of the cell. It was probably the first use of a chemical impermeant probe for quantitative assessment of functional cell surface ligands. It certainly was an early demonstration of functional activities of the cell membrane. It led me later, in connection with studies on mercury toxicity, into the use of mercurials and other sulfhydryl agents to probe the role of sulfhydryl groups, and therefore proteins, in transport activities. My present work on anion transport proteins is in the line of direct descent from the uranium and mercury studies. We developed a series of affinity probes relating to inhibitors of anion transport, which were used to identify the

(a) Correlates to bone and to carcinogenesis are discussed separately.

anion transport protein in 1974. This was probably the first transport protein so identified, although the enzyme Na-K-ATPase had been earlier identified as playing a role in Na^+/K^+ transport. As a consequence of the identification of the anion transport protein, it has become an important model system for understanding protein-mediated transport and the structure of transport proteins. Several hundred papers have been published in the last ten years, a fair proportion from my laboratory. . . . So in summary, there is an evolutionary line from the uranium studies to the anion transport protein.
(Rothstein 1983)

The cell membrane continues to gain in importance in many phenomena, including immunological reactions. While many other fields are now contributing to it, this provides an excellent example of how a career and a field of investigation got their start in curiosity about the mechanism of action of one of the prime elements discussed in this book.

2. Tritium and the Dynamic State of Body Constituents

In discussing the behavior of tritium in chapter 10, and its incorporation into nucleic acid precursors in chapter 20, various cellular mechanistic correlates were described. Of additional interest is a series of investigations with tritium carried out by R. C. Thompson and J. E. Ballou at Hanford in the early postwar years. At that time, biochemists were greatly impressed by the new evidence for mobility of various moieties in body constituents that were previously thought to be more or less static. This had led to much discussion of the "dynamic state of body constituents," based largely upon evidence gained from tracer experiments.

As part of the researches at Hanford into the biological behavior and hazards of tritium, Thompson and Ballou noted that the tritium did not pass through as if it were wholly contained in the body water. This was developed in studies involving the mouse (Thompson 1952), the rat (Thompson 1953), individual tissues from the rat (Thompson and Ballou 1954), and concluded that many body constituents, in the rat at least, were not in a dynamic state at all (Thompson and Ballou 1956).

The fact that collagen seemed to be relatively nondynamic had already been appreciated. This work with tritium indicated that nearly every tissue, but blood, had components to which tritium was bound for very appreciable periods. Also, there were many entities in which this relatively long-term binding could occur. It is not a large portion of the total tritium. Much of it does, indeed, exchange rapidly. However, the presence of the phenomenon led to modification of the concepts regarding the dynamic state of body constituents. It also had significance for the determination of radiation dose, not only for tritium, but for many radionuclides, since the presence of long-term binding has been found for many.

3. Cellular-Level Dosimetry

Dosimetry for deposited radionuclides at the tissue or whole organism level is admittedly complex (chapters 9 and 20). Most dosimetry at the cellular level has been based upon phenomena observed with external radiation sources. Yet, there have been contributions from attempts to understand doses to cells and their components, particularly for the high-LET alpha particles of deposited radium, plutonium, and other important radioactive elements. The hot particle

controversy (chapter 9) did much to stimulate further investigation and calculation. Thus, Barendsen (1964) looked specifically at the proliferative capacity of cells in tissue culture treated with alpha particles and expounded on the mechanisms of action of the different ionizing radiations (Barendsen 1967). Other examples are the estimation of cell traversals by alpha-particle tracks from plutonium in the lung presented in the NCRP "Hot Particle" report (NCRP 1975), the theoretical considerations in the same report, the replacement of absorbed dose by the concept of "specific energy" in a microscopic region (Roesch 1977; Rossi 1967), and related theoretical treatments. A recent review of the whole problem of mean dose versus local dose in the respiratory tract was presented by Cross and Bair (1984).

Recently, Dr. John Little, at Harvard, has extended to internal emitters his technique for studying mutagenesis and transformation in mammalian cells. Among other things, he has demonstrated the extreme effectiveness at the cellular level of elements that emit Auger electrons. Earlier work with these is discussed briefly in chapter 10.

4. Other Cellular Aspects

The possible role of cells of various origins, especially cells in the lymphocytic line, in the genesis of radiation effects has been of great interest.^(a) Much of the work involves external radiation. A good source of summary information comes from the proceedings of a Hanford biology symposium entitled *Radiation and the Lymphatic System* (Ballou 1976). Several of the papers pertain to deposited radionuclides. There are two modes of action of special pertinence to work with these: (1) effects of the radiation from the radioisotope on cells of the lymphocytic line, and (2) the role of various cellular reactions on the distribution and excretion and effects of the radionuclide. The production of lymphocytopenia is a classic result of exposure to external sources of ionizing radiation. It has likewise been characteristic of deposited radionuclides. Much effort has gone into determining mechanisms by varying dose patterns, the nuclides, or both.

Some of the work from the Lovelace Inhalation Toxicology Laboratory is illustrative. Jones et al. (1976) gave graded lung burdens of several beta-gamma-emitting isotopes in fused clay to dogs and studied the effects on peripheral lymphocytes. While the effects were largely as expected in relation to lung burden, dose rate, etc., two of the isotopes produced a prolonged lymphopenia that persisted through two and one-half years after the exposure. The other two did not. This was notable because the lymphocytes were not receiving any prolonged radiation dose except from the deposits in tracheobronchial lymph nodes. Could the occasional passage of circulating lymphocytes through these nodes account for such a persistent depression? This is not a unique observation. It will be recalled that animals in the radon experiments at Rochester showed incomplete recovery of red cell count for a long period after exposure. Another approach was to test the ability of lymphocytes to respond to stimuli such as plant mitogen (Benjamin et al. 1976).

Also, work from Battelle over many years examined the possible mechanisms of induction of lymphocytopenia with plutonium (Ragan et al. 1976, work cited therein and in chapter 9).

(a) Upton (1976) says: "Of all the tissues of the body, the lymphatic system, perhaps as much as any other, symbolizes our reactivity to environmental stimuli."

Chromosome aberrations have been noted in lymphocytes from animals and humans receiving moderately low doses of external radiation. It was thought that the persistent deposits of radionuclides seen in lung, bone, liver, and so forth, might be much more effective in this regard than a single dose of external radiation. Results with both animal and human populations have not been consistent. In some cases, the results encouraged use of chromosome aberrations in lymphocytes as a biological indicator of early cellular change. In other cases, the promise seemed empty. Several of the animal experiments were negative at calculated doses that produced positive results in humans.^(a) Brooks et al. (1976) speculated on these differences. Is the lymphocytic line less sensitive in the animal models used? Are there other chromosome-breaking agents present in some cases and not in others? On the whole, the work with internal emitters, including work in humans with radium (Heogerman, Cummins, and Bronec 1976) does not indicate that blood lymphocytes will be a sensitive indicator of early biological damage.

Turning from the effects of the radionuclides on cells to the effects of cells on the deposition, clearance, and binding of radionuclides or in moderating their effects, we enter another arena. We have already seen that phagocytosis plays an important role in the transport of radionuclides. This may be best portrayed in the action of pulmonary macrophages (see chapter 9). More subtle are the important parts played by changes in immune reactions associated with the cells that interact with radionuclides or encounter biological changes already initiated by them. An interesting example is found in some of the work from Battelle (Frazier, Lund, and Busch 1976). The picture is shown in the abstract of this paper quoted below:

Cell cultures have been prepared from lung and bone tumors arising in beagle dogs following exposure to inhaled plutonium. Evaluation of the cultured cells by commonly applied criteria (i.e., cell morphology, lack of contact inhibitory mechanisms, cloning efficiency, growth in soft agar, and tumor production *in vivo*) indicated that tumor cells were being grown in culture.

Blood leukocytes and peripheral lymphocytes from beagle dogs were tested for cytotoxic effects against several cell cultures. Lymphocytes from normal dogs or dogs with unrelated tumors would not kill the bone tumor cells unless monocytes (macrophage) were present, in which case the leukocyte preparation was capable of mounting *de novo* cytotoxic immune reactions after 3 to 5 days in culture. In contrast, the dogs with plutonium-induced bone tumors had circulating lymphocytes that appeared to have undergone presensitization to bone-tumor-distinctive antigens *in vivo*. Consequently these lymphocytes interacted with cultured cells promptly after encounter *in vitro*.
(Frazier, Lund, and Busch 1976)

Many other examples could be given.

Among the conclusions of the Hanford meeting on radiation and the lymphatics were some complexities and dilemmas (Stannard 1976). For example, cell morphology does not always indicate function. Cells that look alike may serve different functions depending upon their biochemical and immunological history. Conversely, some cells that appear different morphologically may serve similar functions. Lymphocytes are not all alike. It depends on where they have been, what influences they have been subjected to. We can, at present, only guess at many of the interactions of importance.

(a) For example, experiments with radium, plutonium, Thorotrast, iodine.

C. Bone

Undoubtedly the research efforts with deposited radionuclides have contributed more to understanding of the mechanisms of events in bone than any other single area. This is partly because so many radionuclides deposit preferentially in bone; partly because the saga of the radium dial painters and patients and the problems of fallout focused attention on bone; partly because data pertaining to mechanisms were almost automatically produced in the studies of the behavior of bone-seeking radionuclides. There is a very large literature, much of it already considered in earlier chapters. Some, which focused primarily on mechanisms, will be reviewed, in part, here.

1. Cellular and Submicroscopic Events in Bone

The field had a good start before the advent of the atomic age. The fact that the crystal structure of bone closely resembled that of the mineral calcium hydroxyapatite was established by x-ray diffraction measurements in the late 1920s and early 1930s. But it took the investigations with radioisotopes to show that bone was much more than a static supporting structure, even in its mineral phases, and that resorption and remodeling were constantly under way. This was why administered isotopes were found to move about in bone and to be gradually buried in the processes of bone growth. It was in 1935 that Hevesy, using ^{32}P , found that there was rapid exchange of phosphate between plasma and bone (see McLean and Budy 1964). The phenomena of exchange in both bone mineral and in the organic matrix have occupied attention ever since.

The enormous effort with radiostrontium proved the fact that it, like radium, entered bone by exchange for calcium and that there was a strontium hydroxyapatite (Engström et al. 1957). The details of bone remodeling were worked out with elements like radiostrontium, radiocalcium, and radium. Autoradiography with both beta emitters and alpha emitters helped to elucidate the role of the several entities such as osteoclasts and osteoblasts, osteocytes and cartilage in the processes of bone growth.

As soon as the dynamic state of bone was established, it was of interest to see if the mechanisms of action of parathyroid hormone and of vitamin D could be worked out at the cellular or molecular level. McLean and Budy (1964) review much of the evidence, including the idea that there is a second hormone, calcitonin, that takes part along with parathyroid hormone in the regulation of calcium metabolism. Of special interest is a unifying concept developed by W. F. and M. W. Neuman (1958) that all aspects of the action of parathyroid hormone can be explained in terms of its ability to enhance the transport of inorganic phosphate into cells.

This latter work represents another direct extension to mechanisms from wartime programmatic research. Neuman and his colleagues spearheaded much of the biochemical work on uranium at the Rochester Project (chapter 2). This began a lifelong interest in physical and biochemical problems of bone. The work went far beyond the action of modifying factors into basic mechanisms. Let us quote from the summary of the chapter on skeletal dynamics in the Neuman and Neuman monograph:

The three ion-transfer mechanisms characteristic of hydroxy apatite *in vitro*—(a) diffusion in the hydration shell, (b) ion exchange at the crystal surface, and (c) intracrystalline exchange—all occur in the animal, but they are modified under the influence of physiological conditions: new growth, vascularity, remodeling and

maturation of bone, and the regulation of absorption and excretion of minerals in the intestine and kidney. At the histological level the age of the bone structure is the primary determination of its reactivity. The newly forming osteone very quickly mineralizes to nearly 90 per cent of its maximal mineral content, displacing the water of hydration in the process and thus inhibiting the penetration of ions. At full mineralization, physicochemical reactions grind to a virtual halt. Such old, unreactive bone elements compromise the metabolically inert, unavailable skeleton which in the adult animal is about two-thirds of the total.

The continuing maturation of bone imparts an irreversibility to the exchange of ions, and, while injected crystal-seeking radioisotopes show a histological distribution reflecting the patterns of growth and remodeling, the complexity of the overlapping rates of exchange, new growth, remodeling, and maturation has frustrated attempts to analyze these processes quantitatively. At present, it can only be said that the exchange process predominates in short-term (24-hour) observations and that new growth, remodeling, and maturation dominate longer periods of observation. The maturation process is also responsible for the permanence of skeletally deposited body burdens of radioisotopes and the failure of therapeutic procedures to mobilize them.

There is, however, a continuous supply of young, reactive bone made available by growth and Haversian remodeling. This constitutes a mineral reservoir which acts as a buffering system for such essential electrolytes as Na^+ , CO_3^- , and Mg^{++} as well as participation in homeostatic control of Ca^{++} , PO_4^- , and pH. Major shifts in electrolyte balance must be presumed to invoke regulatory mechanisms which are poorly understood. The secretions of the parathyroid glands and vitamin D can be considered to have important functions in these regulatory mechanisms and are considered in detail in the following chapter.

(Neuman and Neuman 1958, pp. 135-136)

The book goes on to consider calcification mechanisms vis-à-vis the role of phosphatase, ester phosphates, and of glycolysis, and, in the case of vitamin D, a role of a renal-induced phosphaturia. There was much that was speculative in this presentation. Much has been subjected to further experimental work by these and other authors. Further details would carry us too far beyond the central theme of this chapter, viz., ways in which the research described in this book involved investigations of mechanisms. Suffice it to say that the work still goes on, much of it in laboratories that were involved with the original MED research operations. The work with radium uncovered quite early the nonuniformity of distribution of isotopes in bone on both a macro- and a microscale and stimulated attempts to uncover mechanisms (chapter 1). In the post-World-War-II years, particularly with needs to understand the story with the isotopes from fallout, such as those of strontium, real advances were made in working out the mechanisms of mineral metabolism in bone. An early example is seen in work at Berkeley (chapters 6 and 8), for example; Jones and Copp (1948).

The Argonne National Laboratory (ANL) group was especially active with studies of bone, in addition to those at Rochester and Berkeley. The Argonne semi-annual reports carried a continuing series of papers on the subject during the middle to late 1950s. Their authorship is given below, and the subjects are given in the reference section (Marshall, Rowland, and Jowsey 1956; Marshall, White, and Cohen 1957; Rowland and Marshall 1958; Marshall and Rowland 1958; Marshall and Finkel 1959; Marshall 1960a,b; Marshall and Finkel 1960; Rowland 1960, 1961; Marshall 1968; Marshall 1970). Published versions can be found in Marshall (1962), and the often-quoted ICRP Publication 20 (see below). Another early example comes from Rochester (Boyd, Neuman, and Hodge 1958). There

are many others laced through this and other chapters. There can be no doubt that all of this pertains as much to the mechanisms involved as to its original objective, bone dosimetry.

The obvious differences in gross and microscopic localization in bone of plutonium and the actinides compared to radium and calcium led to much mechanistic work. Major interest centered for many years on just how the surface-seeking actinides like plutonium attached to bone. The MED work described in chapter 8 established clearly that plutonium deposited on bone surfaces. It was assumed at first to be combining with the organic material of the matrix. There were inconsistencies, however, that led to doubts about this. In the late 1950s, the researchers at Utah attacked the problem with a relatively new technique that permitted the preparation of good autoradiograms of *undecalcified* bone. In rachitic rats, Jee and Arnold (1962) proved that plutonium IV citrate readily passed through the uncalcified osteoid and deposited on the underlying calcified bone surfaces. This accounted for the major portion of the plutonium deposited. A small portion did become bound to the organic matrix. Other work showed that this phenomenon was not limited to rachitic animals and that the early idea that plutonium deposited exclusively on bone surfaces, because it combined with the organic matrix, is wrong.

An excellent summary of the behavior of plutonium in bone at the microscopic level is contained in the comprehensive chapter by Dame Janet Vaughan and her colleagues (1973), especially the section on the pattern of ^{239}Pu distribution in the skeleton (pp. 397-421), the theory and technique of alpha dosimetry with particular reference to the skeleton, and radiation dose measurements from deposition of ^{239}Pu in the skeleton written by Betty Bleaney (pp. 424-451). There are others, but this will suffice.

Relatively recent work on the microdistribution of plutonium is seen in work by Schlenker and Oltman (1981). This was presented at the Snowbird (Utah) Actinide Workshop. Also of interest is earlier work presented at one of the University of Utah symposia (Schlenker, Oltman, and Cummins 1976). These experiments applied autoradiography and alpha-particle spectrometry to samples of bone from three of the plutonium injection cases described in chapter 7. Distinct patterns of distribution could be identified on the basis of fission tracks in the autoradiograms. The kinds of deposits identified were:

- (1) Buried surface deposits—These are associated with bone surfaces that were exposed to plutonium and subsequently covered by the formation of new bone. They often appear as intense bands of fission tracks that are covered by bone layers several tens of microns thick.
- (2) Labeled bone volume deposits (LV)—These are associated with bone volume formed while plutonium was present in the blood. The labeled volume produces a relatively high density of fission tracks compared with the unlabeled bone volume (UV). Tracks produced by the latter are due only to natural ^{235}U . Labeled and unlabeled volumes are always separated by buried surfaces.
- (3) Bone surface deposits (S)—In this category, we include only the deposits on the bone surfaces now in existence; deposits on buried surfaces are specifically excluded. Two subcategories are also important:
 - (a) Deposits on the surfaces of labeled volumes (S(LV))—These begin to accumulate after bone formation stops and are easy to recognize in the autoradiographs because the adjacent bone volumes show relatively high densities of fission tracks.

(b) Deposits on the surface of unlabeled volumes (S(UV))—These accumulate on bone that was formed before injection. The adjacent bone volumes show relatively low densities of fission tracks in the autoradiographs. (Schlenker and Oltman 1981, p. 200)

The conclusions from this work give a glimpse of the complexity of behavior of the actinides in bone, the importance of time, and the gross oversimplification of designating bone-seeking radionuclides as either a "surface seeker" or a "volume seeker," as is done for purposes of standard-setting. The conclusions as given by Schlenker and Oltman are as follows:

- (1) In the absence of bone remodeling, concentrations are not greatly different on endosteal, Haversian canal, and periosteal surfaces of long-bone midshafts, 17 months after injection.
- (2) Endosteal surfaces in the axial skeleton show higher concentrations than do the surfaces in the appendicular skeleton at 15 and 17 months post injection.
- (3) The thickness of volume deposits formed by appositional growth exceeds the α -particle range. Thus, the deposits are "infinitely thick" for dosimetric purposes, and existing surface cells are shielded from intense buried surface deposits.
- (4) Surface deposits are so thin that, for purposes of dose calculation, they can be considered to have zero thickness.
- (5) The secondary surface deposits are of considerable dosimetric significance, even when the plutonium is primarily deposited in the volume of bone. (Schlenker and Oltman 1981, p. 206)

A further analysis pertaining as much to macroscopic as to microscopic distribution, but based upon events at the micro level, was given by Larsen, Oldham, and Toohey (1981) at the same actinide workshop. They are typical of a host of investigations bearing on differences among bones from different parts of the body and within a given bone. A portion of the abstract from their presentation is given below:

The concentrations in most axial bones were factors of 2 to 4 higher than the average in the entire skeleton; the concentrations in the skull bones were about the same as the average, and the concentrations in the appendicular bones were a factor of 2.5 to 8 lower than the average.

Within any particular bone, the concentration in the trabecular portion was always higher than that in the cortical portion; amongst whole bones, plutonium concentration was not correlated with degree of trabecularity. The bone that could be readily taken at autopsy and whose plutonium concentration closely approximates the skeletal average is the clavicle.

(Larsen, Oldham, and Toohey 1981, p. 191)

Again it must be noted that such differences point out that the setting of standards for bone, as if it were a monolithic entity, can be subject to considerable error.

Microanalytical studies of distribution of both ^{226}Ra and ^{239}Pu have become exhaustive. A good recent example is a report by Bruenger et al. given at the International Conference on the Radiobiology of Radium and the Actinides in Man held at Lake Geneva, Wisconsin (Bruenger et al. 1983). The age at exposure has a significant effect on distribution and retention of both elements. The role of processes at the cellular level in these is analyzed.

Much detailed autoradiographic evidence for mechanisms of the changes in bone came from earlier work of the Utah group. Examples are Arnold and Jee (1957) on bone growth and osteoclastic activity as indicated by the distribution

of plutonium, and Jee and Arnold (1961) on the relationship between plutonium distribution and the sequence of histopathologic changes in bone.

The program with miniature swine at Hanford contributed also to the interpretation of mechanisms, as did the later inhalation work with beagles. An important feature described by Clarke (1962) is the role of circulatory changes. He was comparing ^{239}Pu , ^{226}Ra , and ^{90}Sr and found many qualitative differences in their action at the cell level. He noted considerable necrosis of the Haversian system with plutonium and linked it to blood vessel fibrosis. Thus, loss of osteon circulation caused by fibrosis of the medullary vasculature provided an indirect mechanism for the Haversian system necrosis. There are many other examples (see, for instance, the genesis of a polonium-induced lesion in kidney described in chapter 4) where interference with circulation by radiation-induced necrosis from the passage of the radionuclide through vasculature seems to be responsible for fairly wide-ranging effects.

A general review of basic microscopic phenomena in bone and their influence on dosimetry is contained in the monograph by Spiers (1968).

2. Uptake, Retention, and Models for Bone

Evident throughout chapters 7 and 8 and in parts of chapter 1 was the fact that the retention of radionuclides in bone could frequently be described by a power function of time. Since the power function was thought to have no physiological meaning, whereas exponential functions could be associated with compartmental models, there were many attempts to analyze the kinetic data for bone into several compartments and to identify these compartments anatomically or functionally. This has not been notably successful, but much auxiliary information about bone was obtained. The power function kinetics led to development of the only coherent model for behavior of a group of radionuclides in bone—the model for the alkaline earths—usually attributed to Marshall (1963 and numerous references given in the previous section), although it appeared also as a committee report under ICRP auspices (ICRP 1972). Nuances of this and other models are described in Spiers's book, and the need for a comparable model for the actinides was discussed in chapter 16.

It has been proposed that the power function model (McLean and Budy 1964, p. 102) may be more than empirical. Marshall postulated that it can be viewed as a statistical representation of a complex system in a state of dynamic equilibrium and not necessarily a resultant of a set of simultaneous exponential functions of time.

Mineral metabolism, in general, has been markedly advanced by correlates from the researches on bone. Naturally, the homeostasis of calcium has been central to the mechanistic work since it is among the most precisely controlled elements in the body. However, the gathering of information has extended to all moieties involved in mineral balance, both endogenous and exogenous. Numerous examples have been presented throughout the pages of this book.

Plutonium deposition kinetics and their mechanisms have been a central theme. These were analyzed by Durbin, Horovitz, and Close (1972) for the 1971 Hanford symposium on biological implications of the transuranium elements. A digital computer program was utilized to describe the transport to bone and deposition of Pu(IV) citrate . This built upon biochemical research, some of it described elsewhere in this book, elucidating the fact that plutonium is carried in the blood in part in combination with an iron-containing protein, transferrin (Taylor 1973), some of it carried unbound, and that several compartments could

play a role. The abstract of the presentation by Durbin, Horovitz, and Close summarized the proposed mechanisms as follows:

A conventional kinetic model was constructed to describe the transport and deposition of intravenously injected Pu(IV) citrate in the rat. A digital computer program (MIMIC) was used to generate numerical solutions to the differential equations representing the compartment model. Tissue data and information on the rate of Pu-protein binding in plasma were drawn from published sources. The model consisted of two blood compartments, unbound Pu (Pu_f) and protein-bound Pu (Pu_b), assumed to be bound for the most part to the Fe-carrying protein, transferrin (TF); two extracellular fluid (ECF) compartments, Pu_f and Pu_b ; and four effectively non-returning sinks: liver, skeleton, soft tissues and excreta.

The implications of the solution of the model led to the following working hypotheses: (a) Pu_f reacts with protein, presumably TF, in ECF as well as in plasma. The Pu-TF complex is the most likely form in which diffusible Pu is mobilized from parenteral injection sites, and the most likely form in which orally administered Pu is carried once it reaches the plasma. (b) Little, if any, Pu_b is excreted or deposited in the liver. Formation of the Pu-TF complex is probably not a necessary preliminary to liver deposition of diffusible Pu. (c) Both Pu_f and Pu_b are sources of Pu deposited in bone. The surface of the reticulocyte (where Fe is released from the Fe-TF complex) is considered the most likely site of dissociation of the Pu-TF complex. Pu released at that site could either recombine with TF and recirculate as Pu-TF, effectively prolonging Pu circulation, or recirculate temporarily as Pu_f providing the necessary feedback of Pu_f , or diffuse to the most readily accessible bone surface. (Durbin, Horovitz, and Close 1972)

The rates of calcium accretion and loss in various bone diseases have been studied quite carefully and the findings applied to possible mechanisms. The rates vary from considerably above normal (Paget's disease, metastatic carcinoma, fracture, Cushing's disease, hyperthyroidism, and hyperparathyroidism) to considerably below normal (vitamin-D-deficient rickets, hypothyroidism, hypoparathyroidism). The detailed mechanics for these changes in calcium accretion are only partly worked out. Some of the original data can be seen in Bauer, Carlsson, and Lindquist (1961) and in Dymling (1962).

A useful review of the literature on bone during the "growing years" of our subject can be found in the annotated bibliography on strontium and calcium metabolism in humans and animals compiled by Wasserman and Comar (1961). The subject index from this volume, containing 1,161 references is reproduced as note 1 at the end of this chapter. If one considers that this is now over twenty years old, the volume and variety of studies on mineral metabolism accumulated even to that date can be gauged. Spin-offs to mechanisms are legion.

D. Whole-Body Counting

One of the least invasive techniques for measuring radioisotopes in the body is the so-called whole-body counter. It began around problems of bone seekers, with the methods developed for determining the radium burden of dial painters and patients (chapter 1). The methods of the 1930s were sensitive only to about 0.1 to 0.2 μg radium equivalent. The Los Alamos 4- π liquid scintillation counter was sensitive to about 0.0001 μg of radium equivalent or 1% of the total body ^{40}K . The sodium iodide crystal counter at ANL was sensitive to about 0.0003 μg radium equivalent. Naturally, such sensitivity led to many uses beyond determination of radium equivalents. Among these was a considerable amount of investigation into the metabolism of body potassium in adults and children, the

changes with age, determination of body muscle mass, etc., in health and disease. Nearly every whole-body counter, even though financed for practical jobs of determining body burdens of radium or the radionuclides in fallout, was useful for fundamental investigations of mineral metabolism.

A relatively early compendium on whole-body counting was the result of a symposium, *Radioactivity in Man*, held at Vanderbilt University and published in 1961 (Meneely 1961). In addition to reviews of the methodology and its pitfalls, some of the applications to basic biology and clinical medicine are given, along with the practical applications discussed in earlier chapters. The kinetics of retention of, for example, ^{60}Co -labeled vitamin B_{12} were found to be quite different in chronic myelogenous leukemia compared to normal; the retention of ^{85}Sr was quite different in osteomalacia, osteoporosis, and hyperparathyroidism; the absorption of iron from the intestine was quite different in iron-deficient from normal individuals.

A center for applications of the whole-body counting technique to various mechanistic problems has resided over many years in the Medical Division of Brookhaven National Laboratory (BNL) under the direction of Stanton H. Cohn. It began with collaborative work on man with Herta Spencer (see earlier chapters) for investigations into the turnover of ^{85}Sr , influence of dietary stable strontium and calcium on the turnover of bone-fixed ^{85}Sr , and the like. Soon Cohn's studies extended to the turnover of other fallout radionuclides; to studies of iron and vitamin B_{12} turnover; movement of iodine in pregnant and non-pregnant women; composition of various types of bone and the events relevant to mineral metabolism in osteoporosis, thalassemia, Cushing's disease, chronic renal failure, aging, even some forms of cancer. With the decrease in interest in body burdens of fallout radionuclides in the population, the country's whole-body counters have supplied mechanistic bases for a host of biochemical and physiological investigations.

E. Carcinogenesis

It has been said that ionizing radiation is truly a universal carcinogen because in all forms and under a large variety of circumstances one of its long-term sequelae is cancer. A large effort has gone into research on the mechanisms of radiation carcinogenesis. Much of it has employed external radiation sources, since they are easier to handle than deposited radionuclides. Yet, the almost ubiquitous occurrence of cancer of both bone and soft tissue from deposited radionuclides in sufficient quantity for sufficient time has led to many mechanistic investigations with them. We will review some samples in this section that can be considered closely related to the theme of this book. A recent overview compiled by the U.S. Department of Health and Human Services (DHHS 1984) using abstracts is about equally divided between external radiation sources and internal emitters.

General mechanisms of radiation carcinogenesis can be divided into at least four overlapping classes: (1) those involving local origin of the initiating events and the promotional events; (2) indirect changes through regions remote from the site of irradiation (part of the set of phenomena designated as "abscopal"); (3) cases in which the initiating events are induced by radiation, but the promotional events occur largely by other means; and (4) those in which the initiating cellular events are not caused by radiation, but radiation induces the promotional events. While much of the evidence comes from studies using external

radiation sources, there have been important contributions from research with deposited radionuclides. Nearly all of them bear on the role of promotional events, for it seems clear that a single hit from almost any ionizing radiation source may, under the proper circumstances, produce a somatic mutation that could initiate the carcinogenic process.

The accumulated evidence indicates that some radioisotopes that have rather general distribution in the body (e.g., tritium, radiosodium) produce a wide variety of tumors in different tissues. Others (e.g., polonium and thorium) which produce copious amounts of radiocolloids and thus settle in elements of the RES, result in a variety of cancers attributable to the RES. Others that localize in bone or lung or thyroid produce almost entirely tumors or cancers of those organs, except, for instance, where the deposited radioactivity also irradiates surrounding structures. This holds even though the radionuclides in their early stages of distribution may have passed through many other tissues. Thus, the effects seem to be confined largely to the tissues of longer-term retention. The presence of an abscopal effect seems minimal or absent with the highly or moderately localized radionuclides, in contrast to the situation with whole-body radiation or widely dispersed radionuclides. An exception is those situations where endocrine glands are involved, either primarily or secondarily.

A more detailed statement of possible mechanisms for carcinogenesis from radionuclides is contained in a review of the pathogenesis of radionuclide-induced tumors by Casarett (1973) given as part of a Hanford symposium on radionuclide carcinogenesis (chapter 8). In summary, they can be set down in the author's words:

Carcinogenic mechanisms may include events occurring at any time from the prezygotic stage to the time of the beginning of malignant neoplastic proliferation.

The cellular initiating events are thought to be mutations or chromosomal aberrations caused by physical, chemical, or biological (e.g. viral) agents. They involve:

1. Prezygotic (inherited) germinal-cell mutations or chromosomal aberrations persisting in the formation of the zygote and transmitted to many daughter cells of many kinds through the cell proliferation in subsequent development of the organism.

2. Postzygotic somatic-cell mutations or chromosomal aberrations acquired throughout life, with variable degrees of transmission to daughter cells, depending upon the cells acquiring the aberrations and the time of this acquisition with respect to the development of the tissues and organs of which they are parts.

The promoting events are variable for cancers of different tissues or organs. They may be caused by physical, chemical, or biological agents or by pathologic or basic aging processes and may include:

1. Local tissue damage and disorganization, i.e., so-called "precancerous lesion" or "chronic inflammation" in sites of origin of tumors, consisting of parenchymal degeneration and hypoplasia, vascular and interstitial fibrosis, and continued abortive or disorganized attempts at regeneration by remaining parenchymal cells.

2. Normal or enhanced hormonal proliferative stimulation of neoplastically potentiated cells in tissues under special hormonal control, especially in endocrine glands and gonads.

3. Depressed immune competence, which may be especially important in viral carcinogenesis and possibly in carcinogenesis in general.

It is apparent that there are two general classes of mechanisms of carcinogenesis, depending upon whether or not the required promotional tissue changes are located largely in the same locale as the potentiated cells that will originate the cancer.

(Casarett 1973, pp. 1-2)

The fact that we cannot yet separate specifically the two major categories given above bespeaks the complexity of the problem. Nevertheless, some starts have been made, as we will see presently.

The progress of histological changes in both humans and animals has been worked out in detail. Addressing the changes seen in humans with radium, mesothorium, and radiothorium, Casarett (1973) describes them as follows:

The prominent histopathologic changes preceding the appearance of the osteosarcomas consist in the formation of atypical osseous tissue around trabeculae of cancellous bone, the formation of an acellular fibrous tissue in the intertrabecular spaces, and the development of areas of destruction of compact bone with replacement of bone by fibrous tissue. Neoplasms develop in or near areas of proliferating fibrous tissue and atypical osseous tissue. These regions are found especially at the ends of the bones, where atypical bone tissue is most likely to form.

Concerning the changes noted in the large animal experiments, Casarett says the following:

Studies of the bone of dogs receiving single intravenous injections of ^{239}Pu , ^{226}Ra , ^{228}Ra , or ^{228}Th have shown that the histopathologic changes preceding the development of osteosarcomas were similar to those in the radium-bearing human beings. High radiation doses altered the vasculature and circulation, caused bone necrosis and bizarre osteones, bone resorption, reduced bone formation, and marrow fibrosis.

The histopathologic changes preceding the development of osteosarcomas following internal administration of radiostrontium tend to be more advanced in the ends of bones, near regions of endochondral bone formation, and include in their sequence damage and hypoplasia of bone marrow; damage of growing cartilage in regions of endochondral bone growth; development of endosteal tissue hyperplasia and intensified remodeling of bone; development of fibrous hypovascular marrow containing scattered atypical connective tissue and osteogenic cells; subsequent retardation of osteogenesis and bone modeling; dystrophic changes in the osteogenic tissue; the appearance of amorphous and coarse-fibered calcified material in the marrow spaces; production of coarse and atypical immature osteoid or osseous structures in the marrow space; the appearance of atypical, free osteogenic cells with pleomorphic or anaplastic characteristics in the acellular, hypovascular marrow near the abnormal bone or osteoid formations; neovascularization of this tissue; and finally, proliferation of this osteogenic tissue in cancerous fashion, with invasion of nearby structures and metastasis.

(Casarett 1973, p. 12)

Many studies have looked for additive or synergistic effects of radiation and chemical carcinogens and have found both. In some instances, the mechanism of action of the two carcinogens seems to be different. In other instances, there are not obvious differences. Both agents seem to be mutagenic, and this has supported theories of carcinogenesis based on somatic mutations.

Much of the early mechanistic work with radionuclide carcinogenesis concentrated on the influence of the physical and chemical form of the radionuclide, the physical and biological half-lives, the type of radiation (i.e., LET), age, physiologic state, and the like. Except for work pertaining to the uranium miners, formal searches for adjunctive agents were not numerous. It appears that Miriam Finkel and her colleagues conducted some of the earliest experiments (begun in 1961) to search for a possible viral component in tumors induced by radionuclides (see, for example, Finkel, Biskis, and Jinkins 1966; Finkel and Biskis 1969; Reilly and Finkel 1971; Finkel and Reilly 1973). They identified virus-type particles in electron micrographs of spontaneous tumors in mice, injected

the particles into newborn mice, and sarcomas were induced. They called the virus "FBJ" virus (for Finkel-Biskis-Jinkins). They then began a series of experiments in which FBJ virus was injected into newborn mice, and ^{90}Sr was injected later into some mice at different ages. They could distinguish between ^{90}Sr and FBJ tumors by their site of origin, endosteal surfaces for ^{90}Sr , periosteal or parosteal for the viral tumors. Strontium-90 had little effect on FBJ tumors, but the pattern of ^{90}Sr tumors was markedly affected by the virus. Furthermore, the ^{90}Sr -induced tumors were found to contain particles of the virus.

Naturally, association does not prove causation. That has yet to come. Also, there were complications. The tumors induced by extracts from ^{90}Sr -induced osteosarcomas were frequently benign (osteomas) rather than malignant (osteosarcomas), and frequently the extracts were inactive. Also, there were different and larger particles present in some instances, called "RFB-osteoma virus" (for Reilly-Finkel-Biskis), the time of onset of the tumors was different, etc. Yet, on balance, the finding of virus-like particles in every ^{90}Sr -induced osteogenic sarcoma led the authors to conclude there was some meaning in the association.

Some work from Hanford with miniature swine pointed to an association between a virus and ^{90}Sr -induced leukemias. In the swine, there were many more leukemias associated with the daily ingestion of ^{90}Sr than in many of the intravenous injection experiments with bone-seekers such as radium and plutonium. Frazier, Ushijima, and Howard (1970) found virus-like particles in lymph node, spleen, kidney, liver, and blood plasma in the swine bearing leukemia. None were seen in control animals.

Suppression of immune responses in chronic ^{90}Sr administration has also been demonstrated in miniature swine. Such suppression has frequently been implicated as one step in carcinogenesis and is not unusual after radionuclide administration.

Naturally, as alluded to earlier, radionuclides that deposit close to or in endocrine organs may induce cancer partly by upsetting the endocrine balance of the body. This has been particularly noted for iodine deposition in the thyroid. It can bring about not only the changes referable to thyroid function, but effects on pituitary function as both a normal reaction of the pituitary gland to the stimulation caused by the loss of thyroid hormone and direct radiation from the thyroid gland. Thus, tumors may be induced indirectly by the attempts of an endocrine gland to correct for deficiencies in function of a gland it normally controls. These may, in turn, cause more widespread endocrine disturbances at still other sites, e.g., parathyroid, adrenal cortex, ovary, uterus, mammary gland.

Another phenomenon with mechanistic overtones concerns the still-puzzling apparent differences between a radiation dose delivered by a deposited radionuclide and the same calculated radiation dose delivered from an external source. For example, in the case of the longer-lived isotopes of iodine that are less effective than external radiation, it is speculated that their low energy and nonuniform distribution leave significant areas of follicular colloid undamaged. This might account for the lesser effect of these iodines compared to a comparable dose from an external source. Let us not forget, however, that absorbed doses in each case are calculations and not actual measurements at the target cell. Thus, the difference must be viewed as likely but subject to more sophisticated dosimetry.

Much more could be cited to illustrate the contributions of research with radionuclides to the understanding of mechanisms of carcinogenesis, but it would not introduce anything qualitatively new. On balance, it must be said

that much of the work raises as many questions as it settles. The inherent complexity of the genesis of cancer is not made simpler by introducing the complexities of dosimetry, microdistributions, and kinetic behavior of deposited radionuclides at both the cellular and tissue levels.

F. Respiratory System

1. Generalities

It must already be abundantly clear from chapters 9 and 10 and section I of this chapter that the efforts of the internal emitter establishment in the inhalation field were enormous. It is also clear that they led the way for inhalation toxicology in general. Correlates to mechanisms in the respiratory tract have been significant and very broad. They range from situations where the radioactive material served primarily as a tracer for the description of kinetics, particularly of clearance from the lung, to intimate cellular mechanisms. We will cite only a few examples here since much was presented in the inhalation chapters.

General contributions to mechanisms in the respiratory tract developed from the fact that much of the inhalation work was concentrated in centers (chapter 9). The individuals gathered in these centers had roots in respiratory physiology, pharmacology, and pathology, or industrial hygiene and aerosol physics. They were keenly aware of the problems of chemical toxicology as well as of radioisotope toxicology. Thus, the groups at Rochester (the earliest), Hanford, New York University, and Lovelace Inhalation Toxicology Research Institute produced much information bearing on the basic mechanisms in the respiratory system, some of it without even mention of radionuclides.

From the Rochester center, there came the first quantitative appreciation of the role of particle size. Later there was development of general portrayals of the mechanisms of deposition and clearance in twin reviews by Morrow (1960) on deposition and by L. J. Casarett (1960) on clearance, evaluation of the basis of the respirable dust concept (Morrow 1964), and much general aerosol physics and technology (Mercer 1973). On an even broader plane, Morrow chaired and Mercer was a key member of the task group of the ICRP that worked out the extensive and complex lung model now in general use (TGLM 1966; also ICRP 1979). In order to prepare the tables and graphs for this document, it was necessary to select figures for the clearance rates, make various computations from experiments for a large variety of elements in different chemical forms, and to depict deposition in different parts of the respiratory tract. This model, while titled "for internal dosimetry" and thus implying radionuclides, can be applied equally well to nonradioactive dusts and should be. As still another example, we might mention that J. K. Scott and J. N. Stannard, from Rochester, took part in preparation of the National Academy of Sciences (BEAR) report on effects of inhaled radioactive particles (NAS 1961), a report that focused considerably on mechanisms.

From Pacific Northwest Laboratory (Hanford) came careful analyses of the histopathology of areas of the respiratory tract subjected to inhaled radionuclides, including mechanisms of carcinogenesis; much interest in the role of pulmonary phagocytic processes; the effects of adjuvants such as ore dust and cigarette smoke; and, in recent years, extensive studies involving other types of energy generation. The Battelle group at Hanford produced several definitive

reviews that included discussion of mechanisms.^(a) The Hanford symposium on inhaled radioactive particles and gases, chaired and edited by W. J. Bair (1964), devoted a special session to review of the biology of the respiratory tract with papers from several laboratories. Several reviews on plutonium, e.g., Bair et al. (1973); Bair, Richmond, and Wachholz (1974); Bair (1974); Bair (1977); Park, Bair, and Busch (1972); Sanders (1969, 1970, 1972); Sanders and Adey (1970); Sanders and Park (1971); Thompson (1967); and many others that were directed primarily at behavior of inhaled materials included correlates to mechanisms. More recent mechanistic discussions sponsored by the Battelle group include *Radiation and the Lymphatic System* (Ballou 1976), *Pulmonary Macrophage and Epithelial Cells* (Sanders et al. 1977), and *Pulmonary Toxicology of Respirable Particles* (Sanders et al. 1980). Furthermore, W. J. Bair was a member of the relevant BEAR committee and chaired the ICRP task group that produced Publication 31, *Biological Effects of Inhaled Radionuclides* (ICRP 1980). An entire section of this report is devoted to "Tissues at Risk," but generalizations are not yet possible. This is not surprising when one considers that there are more than forty cell types recognized in the lungs and accessory respiratory structures, unevenly distributed, and not isolateable for a cause-effect examination by current methods.

The Lovelace center contributed to mechanisms especially in aerosol physics by the development of monodisperse aerosols that could be used routinely; by studying the influence of physical and chemical state and also of dosage regimen on behavior and ultimate effects of a variety of radionuclides; and, more recently, by extensions to chemical toxicology. They also went deeply into modeling using both computer-generated models and plastic casts of animal lungs. The latter were developed in such exquisite detail that many of the anatomical approximations made from autopsy material could be checked and modified. During his tenure at Lovelace, R. G. Thomas prepared a comprehensive review of the influence of aerosol properties on gross distribution and excretion of radionuclides (Thomas 1964). Among other correlations he made was a log-log (i.e., power function) plot of the time since exposure and the ratio of concentration in lymph nodes to that in lung. The ratio varied from 0.01 to nearly 100, increasing with time. This was a composite plot using four different radionuclides, different forms, and different species. He also reviewed the important role of carrier in retention, a subject much investigated at Lovelace, as well as Hanford. Some drastic effects of carrier could be demonstrated, particularly in experiments where the carrier was the stable form of the radioelement. Since the effect was to reduce retention of the radionuclide at high concentrations of carrier, it was speculated as being due to mass law effects. Also discussed was the frequent finding that even quite insoluble aerosols seem to contain a small but definite absorbable fraction. This led to speculation that there was a mechanism of uptake into the respiratory tract different from those normally involved. Alternatively, there could be a small absorbable fraction normally present that soon became fixed in lung tissue. Other features of the Lovelace contributions to mechanisms are evident in chapter 9 and in subsequent parts of this chapter.

The New York University (NYU) center was deeply involved in the mechanisms of behavior and transfer of fallout radionuclides, as we saw in the

(a) Many of these involved work from several laboratories, but are mentioned here since Battelle was the focal point.

chapters on the environment (especially Eisenbud et al.). Altshuler and Laskin were especially involved with mechanistic aspects of aerosol generation and behavior and with lung modeling. Along with others, they studied the reaction of lung to implanted sources. N. Harley was much involved with possible mechanisms of action of radon and daughters in the respiratory tract. The laboratory director, N. Nelson, was at the forefront of ideas about pulmonary carcinogenesis, as was R. Albert. Best sources of literature are the NYU annual reports cited in earlier chapters.

Occasionally, representatives from the industrial hygiene centers took part in discussions of respiratory mechanisms among the radionuclide people. A good example is the review by Paul Gross (1964) from the Industrial Hygiene Foundation in Pittsburgh on pulmonary deposition, clearance, and retention. Also involved were investigators from the United Kingdom with principal orientation toward nonradioactive aerosols (e.g., C. N. Davies—coal dust). L. Dautrebande from Belgium, father of the medical aerosol, who spent several summers working with the Rochester group, also shared experiences with the internal emitter toxicology people and wrote a comprehensive review on aerosols (chapter 9).

2. Some Details Regarding Pulmonary Radiotoxicology

Chapters 9 and 10 include so many specifics from the inhalation work that bear on mechanisms that little more needs to be said. For the purpose at hand, a few salient points will be reiterated:

a. The role of particle size was of both immediate, practical, and mechanistic import. The effects of particle size on deposition have now become firmly established. Effects on clearance and on toxicity are still found to be somewhat variable, with almost opposite effects seen depending on circumstances (Thomas 1964, and work cited therein and continuing work since). In general, the clearance rate for smaller particles was found to be faster than for large particles, except for material entrapped in upper respiratory passages or pulmonary lymph nodes.^(a) As a result, the translocation from lung to other tissues can be a function of particle size, and, sometimes, with very small particles, tissues other than lung contain the highest concentration even of highly insoluble materials. Toxicity is, in general, greater for smaller particle-size ranges, as described in chapter 9, but this is not universally true. This seems logical where toxic effects (or binding phenomena) are related to surface area, but other explanations must be involved for some situations.

A very common statement among those measuring air concentrations is, "The particle size is . . ." or they ask the question, "What is the particle size?" These are shorthand expressions. Except for the special circumstance of monodisperse aerosols, never encountered in nature or in the industrial environment, the aerosols have a range of particle sizes. The figure given is usually a median and must be accompanied by a statement of the standard deviation. Aerosols with identical median diameters, but quite different standard deviations, will behave differently in the respiratory tract, and many even exhibit different toxicities. The proper question is, "What is the particle size distribution?" However, habits are now ingrained, and all that can be asked is that anyone concerned with pulmonary radiotoxicology never forget that there is essentially no such thing as "a" particle size for practical or mechanistic purposes.

(a) Ciliary transport rate does not seem to be clearly related to particle size.

As described in chapter 9 and presented early by Stannard (1959), the greater toxicity of smaller particle sizes may have a unique explanation in the case of aerosols of radioactive materials. In chemical toxicology, the effects are likely to be proportional to the mass of the material deposited. Carriers (or vector aerosols) are not of great importance except for highly toxic elements. With all but very-low-specific-activity radionuclides, the mass present is usually very low. The activity is carried largely on nonradioactive particles that act as carriers or vectors. There appears to be a tendency for radioactive materials to attach somewhat preferentially to the smaller particles. Also, there are many more smaller particles in an aerosol of a given mass median diameter. As a result, distribution of mass of the vector aerosol may bear little relation to the distribution of activity and thus to the distribution of effects. To compensate for this, radioactive aerosols are commonly characterized in terms of activity median aerodynamic^(a) diameter (AMAD). While regularly appreciated by those with considerable experience, the importance of measuring and expressing the characteristics of radioactive aerosols in terms of activity should be remembered by all, even in routine applications.

The amount of research in aerosol physics behind these and other specific phenomena of basic importance is large, as reviewed in earlier chapters.

b. Before we get too carried away with the importance of particle size, we must recall that changes in physiological parameters, such as tidal volume, respiratory rate, ventilation rate, and the like can have as much influence on deposition as the particle size distribution. This is discussed in chapter 9 and in the ICRP lung model description (ICRP 1979).

c. Another fundamental point derived from the work in pulmonary radiotoxicology concerns solubility. As the work unfolded (chapter 9), it became abundantly clear that behavior in the respiratory tract bore little relation to solubility of a given compound in water. Substances that were hardly soluble at all in water were sometimes found to be cleared rapidly from the respiratory tract. Conversely, some fairly soluble substances were found to be rapidly bound or fixed. Much basic research was done to determine the differences between body fluids and inorganic media in determining the solubility of inhaled materials. Simulants for lung fluids have been developed and used, particularly by Raabe in his days at Lovelace (chapter 9). Nevertheless, no perfect simulant has yet been developed. Fundamental mechanisms of "solubility" in the respiratory tract need further attention.

d. Much work has been done on the biochemistry of the lung. Some of it came from representatives of the efforts in pulmonary radiotoxicology. It is purposely neglected in chapters 9 and 10 because there seems to be little obvious correlation to the behavior of radionuclides or their effects. However, the ultimate effects may rest heavily on some of the nuances of this complex lung biochemistry.

e. The generation of a sophisticated lung model for the behavior of inhaled aerosols was the result of many years of constant attention to pulmonary mechanisms. Even during the MED days, one objective of the work was said to be the development of lung models. The current ICRP model represents a culmination of such work, but it does not stand alone. Alternative models have been suggested and can be used for specific situations. Some of these involve differences

(a) "Aerodynamic" to indicate that the particle behaves aerodynamically like a spherical particle of that diameter.

in detail. Others address the need for application to broader segments of the population and, thus, tap into the reservoir of physiological and pathological information concerning the very young, the elderly, the bearer of a pulmonary disease process, etc. Thomas (1984) is developing a lung model for children of all ages that can accommodate any particle diameter or density, physiological variables, and the like.

f. The pulmonary lymph nodes continue to pose a dilemma. They frequently accumulate by far the highest concentrations of radionuclide in the entire body. Yet, they seem to be far less prone to the development of cancer than many other structures. Only relatively recently have any cancers originating in pulmonary lymph nodes been described, and these are not frequent enough to negate the generalization regarding their apparent radioresistance in terms of carcinogenesis. However, lack of cancer production should not be equated to lack of effect. Profound necrosis of the pulmonary lymph nodes is common. What effect this has on the functions of the lymphatic system generally, and on the cells that happen to pass through, is not clear. As we saw earlier, a lymphocyte reflects where it has been.

G. Radiocolloids and Complexing

Throughout the attempts to understand the behavior of radionuclides in biological systems, there have been persistent indications that the materials were not always traveling as simple ions in solution. It began with consideration of aqueous solutions. The history was described by Schubert (1948). Two aspects were found to be of importance: the formation of complexes (see chapter 2) and of radiocolloids (see chapter 4).

In 1928, Paneth dialyzed water solutions of naturally occurring radionuclides against running water. He found that some passed through the membrane while others did not. He attributed the phenomenon to the formation of colloidal-sized aggregates in the solution. Others, including the influential Otto Hahn (1936), attributed the phenomenon to adsorption of the radioelements on solid impurities accidentally present in the solutions. In either case, a dilemma was posed since both the radioisotope and the "impurity" were in such low concentration that their solubility product should not have been exceeded. But Haissinsky (1934) had already stated, "one cannot apply to these compounds the usual conception of solubility and solubility products."

Appreciation of the importance of radiocolloids developed during World War II at both the Metallurgical Laboratory in Chicago and in Berkeley. As a result of the Chicago work, Schubert (1948) published experimental results along with the historical summary already cited. He described the radiocolloidal properties of some of the fission products using dialysis, ultrafiltration, ion-exchange adsorption, etc. He concluded that whether or not the aggregates were truly colloidal in nature, they behaved like colloids and were about 10^{-6} cm in diameter. Special cautions were issued not to let these phenomena complicate the reproducibility and interpretation of any results obtained using buffered injection solutions (the colloids are less "soluble" near neutral pH) and in interpreting *in vivo* phenomena.

Reports from Berkeley focused on the effects of these radiocolloidal phenomena on behavior of radionuclides *in vivo*. It seems to have started with observations that colloidal calcium phosphate (Jones, Wrobel, and Lyons 1944) was taken up by liver and spleen and was followed by work with some of the

rare-earth-type elements. Dobson et al. (1948) described the differential behavior of colloids of different sizes in mice, rats, and rabbits of elements such as yttrium, zirconium, lanthanum, and columbium. The effort was sufficient to lead to more than academic interest. It was considered possible to selectively irradiate different organs or tissues by manipulation of colloid particle size. Gofman (1949) gave details of the chemical principles and methods for preparation of the pertinent colloids and how they might be of clinical use. Incidentally, it became clear that the colloids once deposited tended to remain in situ for fairly extended periods.^(a)

Schweitzer and colleagues at the University of Tennessee (1952, 1953) called further attention to the importance of radiocolloids in solution and in vivo. There was much interest, generally, in the aggregates seen in lung and bone by autoradiography, whether or not these represented colloidal phenomena *per se*.

The tendency to consider *both* the phenomena in the injection solution and in the organism after injection continued for many years. For example, the Rochester group looked in some depth at the properties exhibited by ^{210}Po , both in vitro and in vivo. This work was described, in part, in chapter 4. A summary by Stannard and Casarett (1964), taken from the concluding comments of the polonium monograph (see chapter 4), tells the story succinctly. It is reproduced, in part, below:

SOLUTION CHEMISTRY AND RADIOCOLLOIDS

The first five papers (6-10) address the behavior of polonium-210 in vitro or in vivo by techniques intended to characterize its behavior as a "radiocolloid" and its combination with biologically important molecules. Using microfilters, Morrow, et al. (6) present data from our early experiments on solutions of polonium. Despite the somewhat preliminary nature of the study, it shows clearly that at physiological pH the element is largely present in a nonfilterable form. By contrast, at acid pH the element is in a more readily filterable form and behaves less like a colloidal hydroxide.

Subsequent studies (centrifugability, settling, etc.) showed properties consistent with the broad definition of a colloid, although the low concentrations of polonium prohibit application of such objective criteria as light scattering. The size may range widely (8), and the behavior may be greatly modified by the presence of complexers as shown in the carefully controlled in vitro experiments of Feldman and Saunor (10). . . .

Of major importance is the possibility that oxolation, after ololation, produces polymers that are accessible only to strongly penetrating complexers after their formation. Thus, once formed, these polymers may persist as entities through many subsequent treatments of the solution and even though initial periods in vivo.

The presence of complexers considerably reduces the number of larger aggregates in solution, which suggests that similar changes occur in vivo, and that the large aggregates do not persist indefinitely. This is exactly what has been found in the autoradiographic studies, both those reported herein (11) and the earlier study of Gallimore, et al. (12). Independent evidence for changes in diffusability is found in the results of Hursh (13) who showed increased dialyzability of polonium combined with BAL (British Anti-Lewisite) and in the basic chemical studies at Mound Laboratory and elsewhere (14). In fact, Stannard and Haydon (15) showed that BAL increased the absorption of orally administered polonium from the gastrointestinal tract, presumably by formation of a more soluble complex in the gut wall.

(a) As we will see later, the aggregates do break up with time, in the case of some elements at least.

The disappearance of intravenously injected polonium from the blood and its appearance in elements of the reticuloendothelial system (7) are consistent with behavior of a material of colloidal dimensions. There can be little doubt that aggregates do exist in the blood after intravenous injection, and that these are removed by and deposited in the reticuloendothelial system. There is ample evidence from autoradiography for their presence (11,12) in blood and tissues after intravenous injection and for their disorganization and disintegration within a day or two after deposit.

An important contrast in physical state in vivo is seen by varying the route of entry. The larger aggregates characteristic of early times after intravenous administration do not appear in blood or tissues after oral administration. They are seen in the gut, however. Thus, the contribution of the large aggregates is entirely absent after oral administration except for the gut wall itself. After inhalation, aggregates can be found in lymph nodes, lung, upper respiratory tract, gut, or phagocytic cells, but almost never in other tissues. . . .

The apparent localization may contribute less to the total radiation dose than might be predicted from casual observation. L. J. Casarett (11) points out that the single atoms or small groups of atoms, ubiquitously present in the tissue sections studied, are much less dramatically emphasized in the autoradiogram than the large aggregate. Careful track counts indicated that less than 20% of the total activity appearing in the autoradiogram was contributed by polonium in the larger aggregates. This was in tissues of an animal receiving "neutralized" solution intravenously and hence having a maximum of larger aggregates. Since the aggregates are disorganized within a few days in vivo, we must conclude that the "hot spot" problem is probably not of large significance, nor is this aspect of the physico-chemical state of the entering solution the primary factor in determining dose distribution except during the initial hours after administration. . . . The fact that colloidal properties such as filterability, dialyzability, centrifugability, and in vivo behavior could vary markedly as a function of pH in a manner similar to that found in macroscopic hydrosols supports strongly the view that true radiocolloids are formed, not just pseudo-colloids due to adsorption on impurities. Yet our data on the addition of foreign particles are not conclusive in eliminating a role of this process also. Both processes may occur and contribute to the general phenomena. In fact, the question may be raised as to whether such phenomena exist quite generally in dilute solution and can be seen with solutions of radioactive materials only because of the unique techniques for measurement of very small quantities inherent in such work. Thus the term "radiocolloid" may have no real meaning except with reference to the methodology. The phenomena may be present in most very dilute solutions whether of radioactive or stable isotopes." (Stannard and Casarett 1964. All references except Nos. 13 and 15 are cited in chapter 4. References 13 and 15 are cited in chapter 19. Each is by author and date rather than by number.)

It is somewhat puzzling that the role of radiocolloids has seemed to receive much less attention in recent years. This may be partly because biochemical binding to various moieties became of more compelling interest. Nevertheless, the fact that these phenomena probably play a role in much of the solution chemistry and biological behavior of nonradioactive materials as well as radioactive materials should have stimulated more detailed research into mechanisms than has appeared in recent literature. It is a very relevant correlation of physical chemistry to biology with emphasis on low concentration chemistry.

We need add little more to the discussion of the role of complexing, binding to cell constituents and cell surfaces in the pharmacokinetics of radionuclides. Examples are evident throughout this book, including the bulk of the chapter on therapeutic removal of radionuclides (chapter 19). Many of the apparent inconsistencies in metabolic behavior and "biological variability" we have noted may rest, in part, on variation in some of the phenomena of complexing.

H. Comments on Section II

Each sophisticated reader of this book would probably select somewhat different correlates to make between the researches reported in the several chapters and the topics chosen for this short section on mechanisms. There are, indeed, correlates to mechanisms throughout, even in some of the most practically oriented areas. The bases for this author's selections were twofold: (1) points that had not been made in the earlier textual descriptions, and/or (2) points that required emphasis by discussion separate from the detailed presentation of experimental findings. The author hopes that the examples are sufficient to give a broad picture of the ways in which understanding of mechanisms has grown from the research, whether or not it was primarily aimed at their elucidation. It should be clear also that the unfolding of mechanisms contributed to and modified the progress of all of the research, no matter what its objectives. Clearly, physiology and histopathology have had to be slighted in this review, primarily because there is so much that it is difficult to say anything without reiterating whole sections of the text. Let us hope interested readers have the patience to ferret these out for themselves in the individual chapters.

III. Unfinished Business

Many occasions have been taken in the text to point out needs for additional work or items that could not be considered sufficiently, or even at all. This section is intended to set out the highlights of some of these, sometimes in a more general context than on the occasion of the original, sometimes in addition to the original. They are presented in three parts that concern, respectively, things that could not be covered, general areas requiring further work, and specifics organized chapter by chapter.

A. Omissions

It has been emphasized that our coverage was biased to work in the United States (see preface). Despite the considerable length of this book, much work

done in other countries has had to be either described very briefly or omitted altogether. General references that include such research make up in part for this deficiency. Some areas where the effort was to a considerable extent, even preponderantly, in non-U.S. laboratories do not suffer from these sins of omission, and the review is essentially global (e.g., chapter 19). In others, there was nothing to report from other countries because at the time the United States was the only country that had the pertinent radionuclides in its possession. Extensive research in the USSR has had to be referenced primarily by citing reviews. Perhaps a companion volume to the present one emphasizing these omitted and truncated areas would be a worthwhile project.

Detailed methodological aspects of much of the research have had to be omitted or given very briefly. The two chapters on instrumentation are, perforce, quite general. There is no doubt that advances in instrumentation and methodology were key factors in the progression of the research, as can be appreciated from chapters 17 and 18. Unfortunately, there have been many occasions when important specifics for a given experiment have had to be omitted to save space. However, it may well be that even condensed descriptions of techniques, such as might have been possible in these cases, would present such a poor substitute for reading the original papers that the best service we can perform is to get the reader into the literature.

It must be emphasized again, as it was in the preface, that this book is a history, not a critical review. Except where rather gross errors or obvious misconceptions may have led to quite erroneous data or conclusions, the work has been described without attempts to extrapolate to what the results might have been if the work were to be done today. No doubt the range of experimental error might be less, the sensitivity of the determinations greater, and the reliability of the figures thus enhanced. This may be particularly true in the area of environmental measurements. Also, interpretations might be different in the light of present knowledge. Nevertheless, the primary thrust of much of what is reported in this book is not unduly dependent on precision of measurement. Some apparent dilemmas might be easier to resolve if the experiments had used today's methods and today's concepts, but we would not be reporting history if that were the case. Thus, the results have been presented in terms of what the authors and laboratories did, what their measurements showed in terms of the methodology used, and the conclusions drawn by those who did the work or reported it. On the whole, we must be impressed by what was done, sometimes under incredible pressure, frequently under the yoke of secrecy, and with evolving methodologies. Undoubtedly, there were cases where even the then-available methodology was not used as well as it might have been. Perhaps some future historian would like to pinpoint these for posterity. On balance, we must be impressed with the relative solidity of the major conclusions of these decades of work.

B. Needed Additional Work

1. General

Before we proceed, a general comment is needed. If one word could be used to epitomize the needs of the future in this field, it would be mechanisms, *mechanisms*, **mechanisms**. The preceding section gave glimpses of many ways in which the internal emitter research bore on or had correlates to biomedical

mechanisms. Nevertheless, it cannot be said that the driving force was the understanding of basic mechanisms, to the extent seen in pure biochemistry, molecular biology, genetics, or even basic radiobiology using external radiation sources. This is not surprising. The inherent difficulties of handling radionuclides in biological systems are very large indeed. Frequently, it has seemed that much of physics, chemistry, and biology was involved in each major experiment, even the most practically oriented ones. Much attention had to be devoted to problems that, while sophisticated and completely necessary, could not reflect directly on the basic mechanisms underlying the observed phenomena.

A simple example is the gastrointestinal uptake of radionuclides. With the need to establish uptake figures for the most important radionuclides under a variety of conditions and in different species, as well as to determine even a single reliable figure for the many hundreds of elements of lesser importance, full attention could not be devoted to the mechanisms involved in gut uptake processes. This must be contrasted with the situations for iron and calcium, for example, where whole careers and major laboratories have concentrated on the mechanisms of their passage through the gut wall and other cellular barriers.

It is this author's view that we now are in a position to do much more purely mechanistic research in the radionuclide field. The major empirical answers are in. A good start has been made on explanations. To realize fully the enormous investment of the past decades, we should look even more for explanations.^(a) This is the true mission of scientific research and could, without doubt, open new vistas not yet appreciated.

It would be easy to urge extension of nearly all facets of the research described in this book. Unknowns remain in all of it. It could not be otherwise; for good research notoriously raises as many questions as it settles, or even more. Yet, in view of the limitations on resources now available, the shift in emphasis toward other areas (the needs are clearly great in chemical toxicology and quite justifiably require attention from some of the same investigators whose work we have been reviewing) and maturation of the field, it would be naive to recommend equal extension in all areas. Some priorities became apparent in preparation of a compendium like the present one. The author will expose a few of his conclusions regarding general avenues for continued work in the balance of this section.

a. Target Cells

The broad range of radiosensitivity of various cell types was worked out in considerable detail many years ago. But the classification applies mostly to the effects of high doses and high dose rates of external radiation. When we turn to low doses and low dose rates and add the complications of radionuclide metabolism, the picture becomes murky indeed. Over and over, attempts at

(a) A pertinent example concerns the influence of valence state. The work during World War II made a start toward determining the importance of valence state on processes such as gut uptake and pharmacokinetics. The chemists soon had far more information concerning oxidation states and the interrelated valence states that could be assimilated for the biomedical experiments. It is time to review much of the experimental work in a more sophisticated fashion (Durbin 1986b).

rigorous dosimetry and understanding of mechanisms came to grief because the true target cells were not known with any certainty. More work with this objective would assist with a wide range of problems.

b. Mechanisms of Carcinogenesis

It cannot be said that the work with radionuclides has contributed as much to developing basic ideas on carcinogenic mechanisms as research with external radiation sources. The problems with radionuclides introduce too many complications. Yet, cancer of organs such as bone or lung at low radiation doses is typically developed through the mediation of deposited radionuclides. We must keep on and find out in depth why certain radionuclides are much more carcinogenic than others and what role, if any, is played by cofactors of various types. The radionuclide field contains some puzzles worth solving in the area of carcinogenesis.

c. Uptake, Distribution, and Excretion—Species Comparisons

In this author's opinion, the enormous bank of information on these subjects needs little further expansion along the lines applied to date. A few notable exceptions reside in metabolic constants for compounds of the more esoteric elements and for behavior in environmental media. Some "constants" are still based on only one or two experiments, sometimes in a relevant species, sometimes not. Recent experience (e.g., with ^{237}Np) has revealed that an element can go from "esoteric" to one of considerable importance in long-term waste disposal on the strength of a substantial change in only one metabolic parameter. The metabolic models used for dosage calculations are slowly being reviewed. When examples of really shaky basic data turn up, the biomedical community should be prepared to provide better information.

Saying that we do not need more of the same is not to be construed as indicating we have all we need. As eloquently described by Durbin (1984, 1986a) and by Wrenn et al. (1985), even in the case of a much-studied element like uranium, we still have many needs. When sophisticated model-making is undertaken, the gaps in our knowledge become all too apparent. Inconsistencies made Wrenn et al. state, "no single model or combination of parameters . . . is completely consistent with the experimental data." Part of this results from uncontrolled variables. Some may never be controllable. However, future experimental work needs to be focused much more rigidly on the scientific hypothesis—in this case, the model being tested. The earlier work was more empirical, even range-finding. That is what we need little more of.

Another exception to the proposition that we are almost surfeited with plain distribution and excretion data lies at the micro level. While macrodistributions are well documented, much more needs to be found out about the behavior of many important radionuclides at the level of microdistribution. If we are eventually to be successful in identifying the true target cells, we will need much better information on microdistribution to accomplish meaningful dosimetry.

It will be realized, of course, that much of our information on uptake, distribution, and excretion is empirical. Complex retention functions have been derived and complex models built, but the exact meaning of the terms of such functions, indeed whether or not they have any physiological or biochemical meaning, is mostly postulate. Research that will do more than describe the behavior of radionuclides in living organisms, but place it in terms of specific

biomedical processes, has been pursued in some areas and with some success. However, much more of our future research in pharmacokinetics should have mechanistic postulates and mechanistic goals and be much less empirical. A few brilliant insights into what is actually going on could save thousands of hours of trial and error.

A persistent problem throughout the research on the pharmacokinetics of radionuclides has been the sometimes large species differences, even between common laboratory animals and between animals and humans. While one solution is to use only data from humans, this has always been difficult. The current phobias toward radioactivity make more such work nearly impossible, except under conditions of accidental exposure or through findings from the constituted registries. A much greater effort is needed to explain why the rabbit or rat may differ from the dog or primate, and when the explanation is found, to determine whether or not the processes responsible do or do not operate in humans. Throughout the preparation of this book, it has been surprising to find how little attention has been given to *explaining* obvious species differences. Good research in this area could have practical uses, but primarily it could help us understand the diversity of nature.

d. Pharmacokinetics in Humans

The need for interspecies comparisons discussed above underlines the need for gathering and utilizing all possible information in humans. Nuclear medicine will supply much information for relatively short half-lived materials. For the rest, a considerable burden is placed upon the few potential sources we have, such as the Transuranium and Uranium Registries, the continuing follow-up of exposed populations such as the Los Alamos workers, and the uranium miners, uranium mill workers, thorium plant workers, and a follow-through to the end of the radium dial painters, patients, and others receiving radium. In the event the future brings unexpected effects to the surface, we would require the best possible information to reconstruct the dose. We dare not muff the opportunity.

e. Epidemiology

If money were available to carry forward only one activity in addition to mechanistic work, this author would probably urge that it be put into sophisticated epidemiology. Measurement techniques are now improving to the point that much larger segments of the population can be assayed for their burden of radionuclides. Thus, much larger samples may be possible. Even failing this possibility, it should be recognized that many of the worker and other exposed populations are now entering the age group most likely to show previously latent long-term effects. The populations are sometimes small, but even so, they should not be allowed to scatter beyond retrieval. The recent entry of some of the uranium workers of World War II into an epidemiologic study is a very hopeful sign. Nevertheless, it must be remembered that many members of this group, as of the groups exposed to radium, can be expected to live into the twenty-first century and that as full and complete a follow-up as possible of them is still required to do a fine rather than just a good epidemiologic study. The same applies with equally long projected times to some of the other important radionuclides.

With emphasis turning more and more to the use of risk estimates for expressing potential health effects from radiation and other agents, the need becomes

still greater for a full-fledged follow-through on the groups now under study and any new ones that may arise. It may be tempting to turn off enterprises in areas where no obvious biological effects have appeared. Let us not forget that incontrovertible evidence of lack of effects in a study carried to its logical conclusion and correlated with good pharmacokinetics and dosimetry may be even more valuable than a shaky positive result.

A word of caution is needed, however. Recent years have provided the author an opportunity to mingle some with epidemiologists. He is inclined to the view that few if any populations in the real world meet the rigid criteria of epidemiologic suitability. Thus, it is possible that none of the precious groups we have taken so seriously would pass muster as first-class epidemiology candidates, though some might come close. Therefore, on pragmatic grounds, we might be wise to continue work in several areas, not just in epidemiology.

f. External Versus Internal Sources—More Microdosimetry

There is no doubt that the complexities of internal dosimetry make comparison of doses from deposited radionuclides to those from an external source quite complex. There has been a general tendency to consider that a rad is a rad regardless of source. This is axiomatic, but cannot be proven until actual measurements are made of the absorbed dose at the relevant target. This has yet to be done. We need instrumentation and methods to do it.

Meanwhile, we are relegated to calculations based upon broad assumptions that by and large by-pass the refinements of microdosimetry. While it is true that the work generated by the "hot particle" controversy has repeatedly indicated that average dose is the most relevant parameter, this is on a gross scale. Microdosimetric approaches for tissues like bone and lung are still in need of a unified approach and a serious effort to determine how much difference it makes whether the energy is delivered at short range by a deposited radionuclide or absorbed from the passage of photons from a relatively distant external source. The reported extra effectiveness of Auger electrons produced in situ is a case in point, as is the difference in effectiveness among the iodine isotopes.

This work may be regarded by some as excessively academic in contrast to some of our other needs. Nevertheless, we cannot separate any observed differences between external and internal sources and among internal sources as being due to differences in localization of the radionuclide, in specific activity, etc., or aspects that may reside in microdosimetry without a more overt attack.

g. Risk Estimates

Present trends make careful derivation of estimates of risk necessary for all of the important radionuclides. A desirable format is the toxicologic approach, viz., direct determination of risk in relation to intake in humans without the intermediary of a radiation dosage calculation. The number of radioelements that give promise of being handled in this way is unfortunately very small, e.g., ^{226}Ra , ^{224}Ra , radon and daughters, thorium isotopes as in Thorotrast, perhaps someday plutonium. Direct estimation of risk through animal experiments may be possible in some cases but has the problem of species differences.

Surprisingly, even with our most extensively studied radionuclide in humans, ^{226}Ra , it has turned out not to be easy to derive a consistent set of risk factors directly from intake or body burden. It is urged that all current and future data

(e.g., from epidemiologic studies, from the Registries, etc.) be gathered and analyzed with a view toward reliable estimates of risk. This includes the all-important follow-through of the radium cases. The external radiation field has been far ahead, but is now stalled by the problems of dosimetry in the Japanese. It is time for an overt effort to help the radionuclide field catch up.

h. Genetic Effects

Throughout the book, it has been apparent that few radionuclides deposit selectively in gonadal tissue. The few cases extant are somewhat isolated and have not been confirmed. Partly for this reason, direct determination of genetic effects in mammals in the manner of the "megamouse" experiment for external radiation was by-passed for decades. Only recently have serious attempts been made to check out the relative effectiveness of internal emitters compared to external radiation in producing genetic effects in mammals. The results to date do not indicate that many big surprises are lurking around the corner. Yet the effort has been small. While no huge expansion is advocated, continuation of work in progress to its logical conclusion and a sufficient checking out to be sure there really will be no surprises are recommended.^(a)

2. Unfinished Business—Chapter by Chapter, Subject by Subject

In addition to the general indications for work yet to be done described in the previous section, a very brief review according to the subject matter of the chapters may provide needed further summary and emphasis. These are in addition to the points made in section 1 above.

Chapter 1—Radium

The Massachusetts Institute of Technology (MIT) radium studies indicated a leveling off of bone cancer incidence in humans at about 30% on a cumulative incidence scale of 100%. The Argonne radium studies and the current analyses by the Center for Human Radiobiology do not show such a clear-cut maximum. It is hoped that the further follow-up of the ^{226}Ra , ^{228}Ra cases will keep this phenomenon in view for further checking. It may have as much input on mechanisms as further agonizing over the shape of the dose-response relationship at low doses.

While the populations are perhaps not epidemiologically as suitable as might be wished, those exposed in areas of the country using water with high natural radium content should not be forgotten.

The mechanisms of two phenomena seen in the animal work with radium have had only partial explanations. Working them out would be of interest, though not of high priority. The first, generation of eye lesions, may be limited to the dog and not be of much practical import to humans. The second, generation of blood-vessel calcification, does not seem to be species-limited and is unique to radium. The mechanism remains cloudy. Why only radium?

(a) Recently, the potential for genetic effects from deposited radionuclides has been reviewed by authors in the USSR (Lyaginskaya et al. 1985). They conclude that the current ICRP limit for nonstochastic effects (0.5 Sv) is not sufficiently conservative for potential genetic effects of some important radionuclides, including plutonium. This may augur for a more intensive effort than is implied above. It is also recommended that the interested reader consult the recently-issued NCRP report on genetic effects of internal emitters (NCRP 1987).

The true risk of carcinoma of soft tissues from radium is not well established. While there is no doubt of the phenomenon, the current data on incidence indicate that it may be a very late effect. The risk figures derived from early experimental data may need revision as work progresses. Also, a greater incidence of soft-tissue cancers seems to occur with ^{224}Ra than with ^{226}Ra . This should be checked out by completion of observations in animal experiments and the exposed human populations.

Finally, early work showed that the retention of radium increased with increasing dose level in all species. The mechanism of this effect should be worked out, since it might have some general implications.

Chapter 2—Uranium

It is hard to believe that after the herculean effort on uranium during the years of World War II and the smaller-scale continuation in the decades since that there is any further work needed. Yet, there are two major dilemmas regarding uranium that persist.

Despite all the work, there seems to be a persistent quandary on whether or not to base standards for exposure to natural uranium on potential radiation effects or potential chemical toxicity (chapter 16). We saw in chapter 2 that heroic measures were needed to deposit enough insoluble natural uranium in animal lungs and for long enough to produce clear-cut evidence of radiation effects. So far as this author is aware, this is still the only documented case of radiation damage produced by natural uranium, except for some implantations of the metal. It never was possible to induce bone cancer. All of this was at very high concentrations. Nevertheless, those proposing standards for drinking water, where it is the soluble, potentially nephrotoxic forms that are important, keep reiterating an intention to use the potential radiation dose as the criterion. There is no new evidence to support this. Indeed, we have new evidence that chronic uranyl nitrate injection in the dog at moderate doses can produce a chronic uremia syndrome (Fukuda and Kopple 1980). Use of the inhalation route did not change things. Using both soluble and less-soluble forms of "yellow-cake," Eidson (1981) at Lovelace found the only site of extensive damage to be the kidneys. Goldman (1981) has stated categorically that "uranium toxicity in drinking water should be based on chemical toxicity and not radiation toxicity." It would seem that a small but conscientious effort could resolve this nagging "dilemma," since it seems hardly to be a dilemma at all.

The second outstanding dilemma with uranium is the lack of correlation between measured amounts of uranium in autopsy and other tissue samples and that predicted from air sampling data. This was discussed in the appropriate chapters but is reiterated here. The accumulating information from the Uranium Registry should help, but it must be accompanied by a much more serious effort to gather, analyze, and evaluate the exposure data. If the whole dilemma is based upon the nature of the sampling and characterization of the workers' exposures, we should be clever enough to find out once and for all. These problems are expanded upon further by Stannard (1984, 1986). Occupational exposures to uranium are not stopping.

As a corollary to the above areas, it should be noted that recent data gathered by Morrow and colleagues at Rochester (Morrow et al. 1982) indicate that the threshold level for nephrotoxicity of uranium in the kidney may be lower than that commonly employed. This, too, needs cognizance in future work. Also, Morrow et al. indicate that the development of tolerance is not a simple or

even a general phenomenon. It is definite when the measure is mortality. It is not so definite by other measures. Finally, this new work shows evidence of effects in many parts of the kidney, not just the proximal convoluted tubule, as considered dogma for many years (chapter 2). The effects are, however, more subtle and perhaps require more chronic exposure or higher concentrations. All of this makes it clear that the uranium saga is far from finished. The recent survey of uranium models by Durbin (1984 and 1986a) attests to this. Also see Wrenn et al. (1985).

In chapter 2, we bemoaned the lack of extended effort beyond the work of the war years, and shortly thereafter, on the higher-specific-activity isotopes of uranium. It appears that there is now little need for further urging. Ballou and colleagues at Battelle have mounted a continuing study of uranium-thorium breeder fuels and are already publishing on the metabolism and long-term effects of ^{233}U - ^{232}U -oxide and nitrate fuel materials (Ballou et al. 1985; Ballou, Case, and Haggard 1984).

Chapter 3—Radon and the Uranium Miners, Radon in Dwellings

The designation of the true target cells, further examination of species differences, and the logical conclusion of the epidemiology already mentioned apply especially to research in this area. In addition, it would be desirable to have much more and better dose-response relationships for the uranium and other miners, and a resolution of the true role of cigarette smoking and of other contributing factors. The present circumstances of lower exposures and fewer miners, while good for the total health status of that population, make it somewhat unlikely that we can expect large expansion of the dose-response data for humans. But we should keep trying. More conclusive evidence of the role of contributing factors is needed via further animal experiments. It would be desirable if these were made part of a coordinated attack on the mechanisms of carcinogenesis rather than done in isolation.

The role of unattached daughter products is much less well understood than it should be.

The recently developed concern about population exposures to radon and daughters in energy-efficient, "tight," buildings has created such a stir that the need for further work needs little urging here. It must be realized that only a minuscule fraction of dwellings or other subject buildings in the United States have been surveyed. Perhaps a more realistic sample is needed to make us more confident about the dimensions of the hazard. This is hardly research that could be put in the same category as understanding the mechanisms of action of radon daughters, but it requires doing. A bit more action is needed, too, on remedial measures. This may be more in the nature of providing information and advice than in performing new research. A concise and very useful general summary of the problems of environmental radon has been published very recently by scientists at the U.S. Environmental Protection Agency (EPA) (Cothorn and Smith 1987).

The need to be alert to opportunities to study populations around the spas was emphasized in chapter 3.

Chapter 4—Polonium and Thorium

While there are many unsolved problems with polonium, most of them are generic and do not require special mention here. Unfinished business with thorium concerns largely completion of the studies with the Thorotrast patients,

a final determination of the role, if any, of chemical toxicity in the action of Thorotrast, and a thorough epidemiologic study of the thorium industry workers.

Chapter 5—Early Days of Manmade Radioisotopes

Unfinished business from these days will be considered in connection with later chapters.

Chapter 6—Wartime Work with the Fission Products

Carry-overs from this work were taken up in chapter 8.

Chapter 7—Wartime Work with the Actinides

Ditto. The expressed need for more cellular-level work was only partly met in the postwar work described in chapter 8.

Chapter 8—Postwar Work with the Fission Products and Actinides

There have to be questions on the future status of the several large experiments begun in the early postwar years and described in some detail in chapters 8, 9, and 13. Briefly, they are nearing their original goals. Some have a few animals remaining. All require more data analysis and preparation of publications, as well as final reports. Furthermore, the results of the several efforts should be coordinated to be sure there are no hidden inconsistencies. Obviously, many leads toward mechanisms were uncovered during the work. These should not be lost sight of (Evans 1983). A good example is seen in a paper by Stover (1972) based on the Utah experiments. There is a formal list of unanswered questions and future research needs. These leads should be assembled now for the benefit of posterity and decisions made on how to follow them through.

Opportunity was taken in 1983 to formally review the life-span effects studies in animals. This was on the occasion of the twenty-second Hanford Life Sciences symposium held September 27-29, 1983, under the ambitious title, "Life-Span Radiation Effect Studies in Animals: What Can They Tell Us?" The agenda included both the long-term experiments with radioisotopes, many of them reviewed herein, and those with external radiation. Nearly all of the U.S. work was reviewed as well as many Western European studies. Unfortunately, there was no real summary of efforts in the Soviet Union. The meeting went for a full three days, and such a volume of complex work was presented that it has only recently been published (Thompson and Mahaffey 1986).

The general reactions were upbeat. These are difficult, expensive, and time-consuming experiments. Yet, I found no investigators who wished they had put their energies elsewhere.

It was clear that the studies had done much more in many instances than was originally expected. In the case, for example, of the several beagle experiments designed originally to check out the relative toxicity of several bone seekers,^(a) much was learned about the basic physiology and toxicology of bone and of the respiratory, lymphatic, and other systems and of carcinogenesis.

The long-term inhalation toxicology experiments (chapter 9) were pioneering efforts that taught us much about the respiratory system and its potential for developing cancer. Very little of the information could have been learned without the experiments.

(a) It is not the fault of the experimenters or experimental design that the relative toxicity figures in the dog were not greatly different from those derived earlier from rodent experiments. Let us be thankful that at least one major dilemma was put to rest. The species were more alike than different.

As alluded to above, information on mechanisms or paths that might be followed in the future toward understanding mechanisms were unearthed. Let it be reiterated that it is the follow-up of mechanisms underlying the phenomena brought to light by these tremendous efforts that is the prime unfinished business from these experiments. Nevertheless, despite the relatively high cost, inflation, and budget problems, the original protocols cannot be markedly truncated without serious diminution of the total yield. It is urged that a national effort be mounted to screen carefully the pros and cons of future work to avoid regrettable mistakes.

Recently, Thompson (in press) presented a short summary of the several large beagle experiments with radionuclides done under the auspices of AEC and its successor organizations, the Energy Research and Development Administration (ERDA) and the Department of Energy (DOE). This is part of a systematic review being done for the Department of Energy. The complete manuscript is awaited eagerly. Only with this in hand can a full and balanced evaluation be made of what, and how much, unfinished business we have before us or should have before us as a result of these life-span radiation effects studies. This is important despite the fact that the efforts have already netted us a position of relative strength considering the reluctance with which nature gives up her secrets.

With the growing awareness of the tremendous job ahead of us in chemical toxicology, it is tempting to suggest that the organizations that have done such a superb job in radiation toxicology simply transfer to this new objective. The shift in subject matter might be difficult for some personnel, and details of the techniques would be different. Yet is this not more efficient than organizing new laboratories?

The shift is already under way in some quarters. The opportunity should not be lost because of possible differences in sponsoring agencies or other administrative complexities. Meanwhile, the organizations should be urged to summarize and publish all facets of their operations with radionuclides and make proposals bearing on mechanisms. As stated in section a. on page 1830, we still cannot explain why one radionuclide appears to be much more carcinogenic than another without obviously different gross pharmacokinetics.

Chapter 9—Inhalation Problems—Radioactive Dusts and Particles

At the end of chapter 9, an excerpt was given of a planning document produced in 1975 by the Division of Biological and Environmental Research of the then-new ERDA. This is reproduced again below for the convenience of the reader

The declaration by Congress on October 8, 1974, to accelerate development of all energy sources to meet the needs of present and future generations, and to make the nation self-sufficient in energy, also directed that public health and safety be concomitantly assured. The generation of new toxic aerosols by rapidly developing energy sources, superposed upon those agents presently responsible for an alarming increase in lung cancer in the general population and severely increased chronic respiratory disease in industry, could rapidly magnify the danger of wide-spread disease caused by inhaled airborne contaminants. This will occur unless a comprehensive program is promptly implemented to define the nature, properties, environmental levels, and biological disposition of these airborne toxicants, as well as mechanisms of pulmonary or systematic disease caused by aerosolization of energy-related materials. Such a program must incorporate 1) identification of inhalation hazards and characterization of their sources, 2) studies of physical-chemical characteristics of air-borne particulates and gases that affect

their physical and biological behavior, 3) evaluation of factors and processes that affect respiratory tract deposition and retention, 4) increased understanding of mechanisms, pathways, and kinetics of biological disposition of deposited agents, including cell-mediated and dissolutive clearance, translocation rates and fractions, and processes of elimination or detoxification, 5) identification of the nature and degree of deleterious effects, both acute and delayed, resulting from inhalation of toxic materials arising from, or related to nascent energy technologies, 6) establishment of primary and sequential dose-effect relationships, 7) identification of sensitive populations and studies of the influence of age or compounding diseases upon effects, 8) predictive models based upon experimental work, 9) evaluation of effects of localized concentrations versus diffuse distributions of inhaled contaminants in critical tissues, 10) mechanisms of repair and recovery.
(ERDA, DBER 1975)

Progress has been made, but much remains to be done. The true explanation for the unique carcinogenic effectiveness of some radionuclides in lung, for the lack of carcinogenesis in general in pulmonary lymph nodes, and the many problems of the respiratory system outlined earlier remain for the future.

Chapter 10—Inhaled Gases

Unfinished business with the noble gases, tritium, iodine, and related entities resides mostly at the cellular level and is mechanistic. The reason that a transmutation effect should appear with tritium only when the labeling occupies very specific sites is not known. Nor is the dosimetry of some of these very low-energy beta emitters very well understood. It appears unlikely that the general problems raised by these considerations will be neglected so long as molecular biology continues in its state of eminence, but it will require also the special touch of the trained radiobiologist.

Chapters 11 through 15—The Environment Chapters

The unfinished business regarding environmental aspects of the transport and effects of radionuclides is taken up in more than usual detail in each chapter. A few generalizations remain to be made. The vastness of the world environment and of the biosphere make it likely that we have more unfinished business here than in any other aspect of the radionuclide field. Unfortunately, ways to get firm answers are not clear; certainly not easy. They are complex, expensive of manpower and money, and international in scope. Also, they are strongly interwoven with our general environmental problems, since the ecosystem is responding to all stimuli simultaneously. With the decrease in levels of worldwide fallout and strict controls on nuclear installations, it must be said that the problems of the environment from radioactivity may be less pressing than many others, e.g., pesticides for agriculture, industrial pollution, and smog.^(a) Yet, the relative ease of measuring the movement of radionuclides, the tremendous start we have in radioecology, and the needs to understand mechanisms foster continuing research in the field.

(a) This was written before the Chernobyl incident and the special addition to this chapter on that subject. There will, no doubt, be a recrudescence of research on the passage of radionuclides through the environment. Nevertheless, it can still be said that we have a better grasp of what needs to be done than in the case of chemical contaminants, and are relatively further advanced.

Among the reasons for continued effort are the following:

1. It was clear from chapters 11 and 12 that the ecosystem approach to assaying possible effects of small increments in radioactivity presents a formidable challenge. No clear-cut changes have yet been seen except in localized areas. We are inclined to concentrate on man and to avoid a frontal ecosystem approach. Present indications are that the potential problems from present levels of radioactive contamination are small. Yet, the experts are at work and aware of the possibilities for surprises. Even though they seem unlikely at present, vigilance should not be relaxed.
2. Consideration of the environment has focused attention on population in contrast to occupational exposures. This means a much broader base is needed in terms of the characteristics of "reference man," the validity of the critical pathway and critical population concepts, and a much more organized approach to the effects of disease states and physiological variables. We have a good start, but much more is needed.
3. In the reconstruction of the doses from fallout around the Nevada Test Site, many ingenious approaches have been taken, as well as a prodigious effort at sifting through mountains of data. Much of this remains in special archives that may be lost when the current pressures from litigation ease. It is urged that documentation in a permanent, relatively concise form be considered and current activities be carried as far as they usefully can.
4. The researches stimulated by the problems of fallout uncovered important biological facts and made very respectable progress in understanding mechanisms. Examples are the presence, magnitude, and explanation for discrimination factors and also of concentration factors; the importance of soil chemistry and physics; and much new information on plants and their role. Yet the story is incomplete. Some of the concentration factors, for example, are based upon only incidental findings and may be confined to only one or two observations. Radioecologists are aware of these needs but may need further encouragement.
5. Obviously, the problems of long-term waste disposal command much attention. Low-level radioactive waste seems, to this author at least, to be more a problem of human cursedness and political considerations than bona fide technical issues. However, the problems of environmental transport from currently active medium- to high-level waste disposal sites require further scientific attention. The choice of eventual new repositories now seems less a technical problem than it did a few years ago.
6. Turning to environmental transport, in general, not just waste disposal problems, we must return to chapter 15. The complex and sophisticated models for environmental transport of radionuclides have far too many "default" values. Before these get embodied into established procedures and their tentative nature forgotten, the biomedical community should be able to supply many more carefully measured and reliable figures.

Chapter 16—Internal Emitter Research and Standard Setting

In addition to the need for strengthening some of the metabolic constants used for computation, already mentioned, there is much unfinished business in the validation of our current standards. As the several epidemiologic enterprises bring in further information, their bearing on the validity of the standards derived earlier should be kept constantly in mind. Furthermore, the need for valid risk estimates requires considerable attention, as was described earlier.

The atmosphere of contention and litigation currently upon us cannot help but produce further challenges to the adequacy of radiation protection standards. The fact that some of the input data were sparse and crude in the early days should not be allowed to cast doubt upon a system that has been, on the whole, adequate, and in many areas, superior. Let us gather and introduce better metabolic data where needed. Conversely, let us waste no more time on empirical approaches to finding effects at the very low doses associated with the standards. Learning the intricate mechanisms of radiation effects at low doses presents greater promise for both external radiation sources and deposited radionuclides.

Bioassay, by either excreta analysis or whole-body counting has been alluded to in many connections, e.g., excretion kinetics worked out during the war years (chapters 6 and 7); postwar expansions and modifications of these (chapter 8), and some brief references to determining body or organ burden in chapter 16. We have not expanded upon the subject since it was more a regulatory and assessment enterprise than research, even though the basic information was derived from the research activities. One of the problems has been that the instrumentation and methodology were frequently strained to or below their detection thresholds. Also, variability was great at the low levels associated with allowable or below organ or body contents. Recently, several ultrasensitive methods for radionuclides of interest for bioassay have been developed. These include instruments well beyond the types described in chapters 17 and 18. The potential of these for bioassay procedures is important for the future. The need for bioassay will not go away.

Chapters 17 and 18—Instrumentation and Methodology

Despite increasing sophistication and miniaturization of instruments, it appears that further improvements in reliability are still needed.

One need that this author intended to stress appears to have been met recently. This is the need for a survey instrument with a range of several orders of magnitude that would not saturate in a strong radiation field and give false negative results, yet be sensitive at fractions of the maximum permissible concentrations. Such an instrument is now available. There are probably many other needs that the instrument makers are hard at work on.

It appears likely that the enormous demands made by nuclear medicine on the instrument makers will ensure continued progress in measurement of radioactivity, but we should not depend too much on the needs of nuclear medicine. We have our own needs.

Chapter 19—Therapeutic Procedures for Deposited Radionuclides

The outlook for therapy would be greatly enhanced if agents or procedures were found that could pry loose radionuclides that have become "fixed" in the tissues. At present, we are handicapped by the need for prompt action, even before it is clear whether or not therapeutic removal is indicated. However, the prospects for such a major breakthrough are slim. We are flying in the face of basic phenomena of biochemistry where any effective agent might well disrupt as many normal bonds and complexes as it did the abnormal, "foreign," objects. Yet, the need must be cited and kept in mind for future reference.

It was obvious in chapter 19 that much more could be done on the basic pharmacokinetics of chelating agents and in the synthesis of new compounds. It is likely that this enterprise is well in hand in the cognizant laboratories,

primarily those abroad, without a special reminder here.^(a) The search must include not only better agents with higher therapeutic ratios, but special attention to the embryo and fetus, if present; the effects of age; and, especially, the influence of underlying disease processes.

A corollary to such developmental work is the need to maintain a corps of physicians and radiation protection experts that can respond quickly to unexpected contaminating events and make early estimates of the potential need for therapy.

Finally, as urged at the conclusion of chapter 19, we need to become better prepared for instances of population exposure to radionuclides, in addition to the more conventional occupational event.

Chapter 20—Selected Aspects of Nuclear Medicine and Tracer Chemistry

The broad front of activities in nuclear medicine is almost certain to encompass any ordinary unfinished business made apparent in the chapter. The objectives of the clinician, of the investigator interested in the behavior and effects of radionuclides, and of the radiation protectionist are essentially concurrent in this field. Toward the end of chapter 20, promises for a possible new era were mentioned. There was envisaged a recrudescence of therapeutic uses as well as continuation of the enormously useful diagnostic modalities. Tentative forays into new areas such as monoclonal antibodies, in-situ production of therapeutically useful radiation doses from neutron interactions with stable isotopes, and others were mentioned. The talents now available combined with methodologic breakthroughs may be able to reverse the discouraging experiences with radionuclides for therapy encountered in the middle to late-middle decades of this century. The basic idea of placing a significant dose in a significant area by means of a radionuclide attached to a suitable carrier is worth further exploration.

IV. Further Commentary—Chernobyl

A. Background and Need for Discussion^(b)

The manuscript for this book was completed when the nuclear reactor accident at Chernobyl in the Soviet Union occurred. The author and sponsors thought this major event involving exposure of a population to the fission products from a nuclear power reactor required specific comment as part of this final chapter. In accord with the plan of the chapter, we will look at both retrospective and prospective aspects. Did the years of research and field work described in part in this book make the task of reacting to this major emergency easier and surer?

(a) The U.S. effort has been drastically curtailed by budget cuts.

(b) This author's initial review of the facts about Chernobyl was greatly facilitated by W. J. Bair by provision of data from the International Atomic Energy Agency (IAEA) meeting (1986), a lecture by Marvin Goldman to the San Diego chapter of the Health Physics Society, a prepublication copy of Dr. Merrill Eisenbud's review for the third edition of his classical text (Eisenbud 1986), and references contained in those documents. Also, two World Health Organization documents (WHO 1986a,b) have been noted. Details have been inserted in the references. Later, Dr. Bair chaired an interlaboratory task group sponsored by the Office of Health and Environmental Research, Office of Energy Research, DOE, which issued a report in June 1987 (DOE 1987). The year 1987 also saw numerous open literature publications, some of which have been added to the prepared text if needed.

Did the knowledge gained, in the decades of biomedical work we have discussed aid in making projections of future potential effects? If so, to what extent? Did the accident expose serious gaps in our knowledge, and if so, what? Were there any surprises, major or minor, i.e., events not predicted by the body of knowledge at hand? Is new research required to assist future generations?

Finally, it seemed that the reader might appreciate a brief listing of chapters in the book that bear significantly, in historical context, on the problems of Chernobyl.

B. The Event

The event itself has received such wide coverage that no need is apparent to repeat a description in detail here. Suffice it to say that we are referring to the accident in Unit 4 at the Chernobyl power station on the Pripjat River about 90 km north of Kiev, one of the USSR's largest cities, and close to the town of Pripjat, population about 45,000. It occurred in April 1986. The reactor was destroyed following a set of operations that went far beyond normal procedures. The resultant steam explosion and fire released about 50 MCi of fission products in particulate form and another 50 MCi or so of radioactive noble gases such as radioxenon, radiokrypton, radioargon, etc. (IAEA 1986). It is stated that about one-fifth of the total iodine inventory was released, about 12% of the cesium, and a few percent of the other normally nonvolatile radionuclides.

The biomedical problems involved exposure to ionizing radiation doses from the radioactive materials in the cloud; heavy contamination of skin and clothing; trauma and burns to those directly involved in the accident and fighting the fires; external doses from fission products deposited on objects and on the ground; and actual plus potential radiation doses to internal body organs through uptake through the skin, and by inhalation or ingestion of radioactive materials of many kinds. Not all of these problems applied to all persons involved, obviously. The close-in doses, particularly from the cloud passage, could be very high, while those from the cloud at considerable distances could be considerably lower. All of the external doses decrease fairly rapidly as a power function of time. Except for workers and fire fighters with gross contamination of skin and/or inhaling highly contaminated air, the problems from radionuclides deposited in internal organs would be (and were) less acute but longer lasting. The intakes might even increase with time because of recycling in the environment (chapter 15) and possible solubilization of the contaminants over time. The environmental contamination aspects will require a considerable period to unravel.

The Soviet report (IAEA 1986) describes the radiological considerations in three categories: (1) on-site, (2) areas within 30 km, and (3) in European portions of the Soviet Union. Others have described radiological measurements in European countries outside the Soviet Union and the measurable but biologically unimportant contamination from vestiges of the plume in North America and Asia. Obviously, these divisions correspond only roughly to the degree of contamination due to the absence or presence of precipitation, variations in wind patterns, and other meteorological factors that could produce large differences in local depositions.

As pointed out in detail by others, the graphite-moderated Soviet reactor design has few counterparts in other countries. The British reactor at Windscale is graphite moderated, as is the "N" reactor at Hanford in Washington State and

other old reactors, many of which are now retired; however, there are major differences. The accident at Windscale, described in some detail in chapter 11, might be considered a small-scale prelude to Chernobyl. However, the graphite fire was limited, the reactor was not destroyed, there was no explosion, and the releases involved primarily the most volatile fission products, e.g., ^{131}I and the noble gases, along with much smaller amounts of ^{137}Cs and radiostrontium. The totals were in the thousands of curies, not megacuries.

The magnitude of the releases from Chernobyl did not approach the total of releases of fission products to the atmosphere from weapons testing. However, some local deposits in the USSR are said to exceed the total deposition measured in that area from all of the weapons tests (Eisenbud 1986; IAEA 1986).

There is no doubt that Chernobyl was a major event, by far the most costly accident to a nuclear reactor in history in terms of both lives and money. Further details from the point of view of a physicist can be seen in Wilson (1987).

C. Was Our Knowledge Sufficient to Cope with the Sequence of Events?

In broad terms the answer is positive.

Physical events at the reactor were, sadly, largely predictable. The motivation for the removal of one safety measure, or device, after another is beyond our scope, and not predictable. However, the physical events, knowing the characteristics of these particular graphite-moderated reactors,^(a) cannot be said to have gone beyond the knowledge of those most versed in their characteristics and behavior. Other nuclear accidents have been attributed, in part, to failure of specific parts or systems to operate as-designed. This cannot be said of Chernobyl, except for a few small details.

The huge investment of time and effort in depicting the acute radiation syndrome by experimental work in the laboratory, field tests in the weapons-testing program, experience with the Japanese bombings, and the few accidents involving criticality or medical mistakes, made prediction of, and reaction to, the acute effects reasonably certain. They were complicated, however, by skin contamination, radionuclide intake, and in some cases, trauma.

The same body of knowledge, with the addition of information from partial body radiation for cancer therapy and other maladies in humans and animals, contributed to understanding what to expect in terms of subacute and long-term effects.

The estimates of risk, developed primarily from studies of external radiation sources, but modified by other studies including intake of radionuclides and application of the linear no-threshold dose-response relationship chosen for standard setting (chapter 16), made prediction of long-term effects possible. It is true that predictions of the total number of cancers to expect in the exposed populations have varied rather widely, especially in the earlier period after the accident, but these variations reside more in the degree of conservatism utilized by the predictors than in uncertainties in the risk factors

(a) For example, a positive void coefficient, a unique property of the RBMK reactor design, not present in Western counterparts.

themselves. Nevertheless, quantitative prediction of truly long-term effects in heterogeneous populations must be considered as one of the weaker points in the application of current knowledge. We need more, including the continuation to their logical conclusion of the epidemiologic studies now under way in the external radiation field, and with deposited radionuclides and the revision of the dosimetry of the Japanese bombings.

The experience with tracking and measuring fallout from nuclear weapons tests made tracking the plume from the accident almost routine. Whether or not the total biomedical toll of the weapons tests is considered to overwhelm the advantages of having this knowledge, it can be said that we did know how to track the plume and its associated fallout. Details can be found in chapter 12.

The constant surveillance of the environments around nuclear reactors throughout Europe gave the first alert that something was amiss. Many very early measurements were done at nuclear energy installations, while more extensive forces were being assembled.

The considerable experience with behavior of fission products in organisms and in the environment had already given reasonable approximations to use for calculating uptake from lung or gut, subsequent tissue distribution, retention and excretion kinetics, and thus potential dose hazard. Factors for environmental transport are also numerous and well-documented. However, the complexities of the environment and the usually low levels of radioactive contamination of it make for somewhat greater uncertainty in predicting long-term behavior and effects.

Contamination of food and water were thought of immediately, and rather prompt measurements of milk, for example, were instituted. This was important for iodine isotopes appeared very early in large quantities. Subsequently meat was sequestered and some cattle butchered before accumulations of radioactivity reached unacceptable levels. Literally thousands of laboratories could be recruited with instrumentation and techniques developed for the routine monitoring of food, water, and the environment. Most of this preparedness comes from the type of work described in the environment chapters, e.g., chapters 11, 12, and 15, and parallel work done in the Soviet Union.

The behavior of radioiodine was well established by work in both the environment and in medicine. Indeed, much of what we needed to know was depicted in the experiments, described in chapters 8 and 10, even as early as the Hanford biology symposium on radioiodine held in 1963 (chapter 8).

The effects of soil type on the movement of radionuclides into plants, especially the anomalous behavior of cesium, were known from previous work with fallout, in the USSR, in the Caribbean (Jamaica), and in experimental work in the field and in various laboratories (chapters 12, 13, and 15).

Possible prevention of radioiodine uptake in the thyroid was begun very early in the on-site population by giving stable iodine. This was based solidly on earlier experimental work and much planning in medical and administrative circles concerned with reactor safety. The promptness of the administrations demonstrated well the lessons learned fully for all prevention and therapy for radiation effects, viz., time cannot be wasted (chapter 19).

The special problems of residents of the arctic and subarctic regions where a very short food chain exists (lichen-reindeer-humans) are serious, if not catastrophic to their way of life. Nevertheless, the phenomena are reasonable extrapolations of information gathered earlier in connection with fallout (chapter 15).

We have a reasonable hold on the extent to which we can generalize from one element to another, and the limits to which application of the generality "mixed fission products" can extend. We know it is best to handle each element, even each chemical form, as an entity, where possible. But we know this is not practical and can fall back on generalized behavior of groups of elements, or critical elements, as worked out for weapons fallout (chapter 12) and research growing from the field tests (chapters 13 and 14). We do not know very well how much error may be introduced by selection of critical radionuclides, critical pathways, or critical populations. We can be assured, however, that such selections will have to enter to some degree.

Obviously, we have learned fully that it is not enough to protect against, or calculate, the dose from cloud passage alone. We saw at Chernobyl no repetition of the neglect of internal dose that characterized the thinking around the early weapons tests and early estimates of reactor accident consequences (chapters 11, 12, and 15).

Relatively sophisticated and rapid computer programs are available for calculation of both external and internal dose. These will suffice for "ballpark" figures. More detail is needed, however, for specific sites and exposures.

Finally, we can feel reasonably assured that no unexpectedly devastating effect will occur in the environment, except possibly locally, as a result of the accident. This comes from careful environmental work, still in progress and needing extensions.

Let it not be concluded that we had all the knowledge that might have been desired. Only the future can tell how well our present knowledge has really served us. It is hard to imagine, however, what our situation might have been had the enormous efforts in radiation biology, radioecology, and toxicology, plus the adventitious contributions from radiology and nuclear medicine (chapter 20) not been supported and pursued with enthusiasm as described in part in this book.

D. Any Surprises?

Obviously, a major event like Chernobyl would be expected to reveal surprises and point up gaps in our knowledge. Let us look first at the category of surprises.

To some, the greatest surprise surrounded the circumstances of the event (Eisenbud 1986). Human error has underlain other reactor accidents, including Three-Mile Island and some of the large chemical releases of recent years. As the Soviets described (IAEA 1986), many of the steps taken by the operators before the explosion were unauthorized, and thus, technically "errors." However, the basic design of the reactor (positive void coefficient) was a very important ingredient in the response, and this was not only well-known but is not a characteristic of most other designs of graphite-moderated reactors. Thus, in retrospect, the fact that the event took place cannot be regarded as a genuine surprise.

The release of substantial amounts of the inventory of fission products was no surprise. Yet, in view of the high temperatures and extent of involvement of the reactor core, the fact that the estimated release was calculated as only about 3.5% of the reactor inventory is somewhat surprising. The relatively small release of strontium isotopes and of actinides accounts in part for this fact, and is probably to be viewed as at least generally unexpected, if not surprising, to the

experts.^(a) There was little need at Chernobyl for our storehouse of knowledge about the bone seekers (chapters 8 and 13).

In the context of the early studies, the role of cesium was, perhaps, of even greater significance than expected. We learned from experience with the long-term contamination of the Marshall Islands and Nevada Test Site that cesium could assume a dominant long-term role, even with weapons fallout. Reactor discharges confirmed the idea. Nevertheless, the concentration of the longer-term biomedical problems on cesium and related elements was not fully predictable. In contrast, the role of the radioiodine was classic both qualitatively and quantitatively.

It is too early to hazard more than a guess as to whether or not there will be surprises in the biomedical area. The early effects were more or less classic. Only as the longer-term effects unfold can we compare biological effects with predictions.^(b)

The same applies to experiencing surprises in the area of environmental transfer. However, the potential for many surprises in this area seems large. The data base for the computer models is quite idealized and generalized (chapter 15). It may or may not fit the circumstances of Chernobyl or the environment of northern Europe.

E. Gaps in Our Knowledge and Need for Further Work

We will consider primarily the biomedical areas, first looking back and then looking ahead to future needs.

Probably the most obvious gap in the biomedical area concerns cesium. As described in detail in chapters 8, 10, 12, and 13, we concentrated our experimental work, for good reasons, on external radiation, the bone seekers, and on iodine for serious examination of long-term biological effects. Long-term, low-level experiments with cesium isotopes were not done, although there were fairly extensive experiments at ANL, at Lovelace Inhalation Toxicology Research Institute, in the USSR, and elsewhere at moderate to high levels of cesium. Whether or not we are safe in assuming (as was done) that, because of its more or less uniform tissue distribution, the cesium effects will imitate those of prolonged whole-body external radiation at low levels, can now only be speculated. It would be comforting if cesium had been inserted in one of the "king-sized" experiments (chapter 8). Mounting of a full-scale experiment now is of doubtful value, however, since the information may be coming in from the exposed populations before such an experiment could be completed.

Clearly, the Chernobyl incident requires a full-scale epidemiologic investigation of the populations exposed. If properly done, an important counterpart to the studies of the Japanese and the radium dial painters and patients might result, thus filling in our knowledge.

(a) Perhaps the attempts to put out the graphite fires by dumping sand, boron compounds, etc., contributed to this (W. J. Bair, January 22, 1987).

(b) Despite the fact that actual data were available only for the early effects, the urgency to make estimates of the biological consequences spawned several evaluations and predictions in 1987. The chapter by Goldman and Catlin in the DOE report (DOE 1987) is quite detailed, but there are abbreviated versions, too (Goldman 1987a,b; Hull 1986, 1987a,b; Marshall 1987; Norman and Dickson 1986; and Gofman 1986). These do not all agree with each other.

Environmental transfer functions must be determined in depth. The knowledge is needed to handle properly the inevitable problems of food and water contamination. It would be very surprising if deviations from the models did not appear in quantity. The next few years provide an opportunity to check out the extant models in the context of the specific event.

Many less important, or less obvious, gaps in our knowledge and needs for further work will undoubtedly appear. However, the biomedical story must unfold first. Meanwhile, the physicists and engineers can busy themselves with the gaps in their knowledge.

F. Where to Find it

To illustrate the general progression of our ideas and of the researches to test them, many specific events were considered in moderate depth in this book. These descriptions, plus the literature cited, may be useful to the reader interested in reviewing, in historical perspective, the development of information pertinent to nuclear energy and nuclear power reactors.

The chapter outlines should be sufficient to guide the reader, but may need to be supplemented by use of the rather extensive subject index. Also, the reader is reminded (see preface) that the scope and mission of this book led to emphasis on U.S. work with, however, frequent references to work in other countries.

1. Physical Events

The phenomena of nuclear fission and the contrast between weapons-produced fission products and reactor fission products are touched upon in chapters 6, 11, and 12. The phenomena of weapons fallout and transport are reviewed briefly in chapter 12, with references for detail. There too are short descriptions of local, tropospheric, and stratospheric modes of transport and the problems of local, nationwide, and global fallout.

Releases of noble gases, of tritium, and of the iodines from reactors and nuclear installations, and transport of the plume are described in chapters 10, 11, and 15. Behavior in the field of released fission products and actinides appear in chapters 12, 14, and 15.

The need for a containment factor as high 10^{-9} is pointed out in connection with the hypothetical Liquid Metal Fast Breeder Reactor, along with a short discussion of our ability to achieve such nearly absolute containment.

2. Phenomena in the Environment

The transport of radionuclides in air, surface, and ground water, and in terrestrial media are considered in chapter 15. Here it becomes obvious that much must be done by modeling. The principal features of environmental modeling are considered in that chapter, with examples involving specific radionuclides.

The contamination of food and water and their possible importance are considered in several places. The basic revelations appear in connection with fallout from weapons tests in chapter 12. Experimental work involving food chains, including soil, is described in chapter 13. This includes individual nuclides and individual organisms. Dietary pathways and dietary usage factors appear prominently in chapter 15. Special environments are considered in both chapter 13 and chapter 15.

Knowledge of the behavior of radionuclides in aquatic environments is diffused through several chapters, primarily chapters 11, 12, and 13. These include the Pacific Ocean and several river systems. Possible effects in environmental systems are spread throughout chapters 11, 12, 13, 14, and 15, but are considered especially in chapter 13.

Environmental experience around nuclear energy sites is concentrated in chapter 11, but some of the polemics generated are reserved for chapter 12, since they involved weapons testing as well as nuclear installations.

3. Generation of Biomedical Information

The early experiments with fission products done during World War II are discussed in chapter 6, while the more sophisticated and long-term experiments with animals are reviewed in chapter 8. These include the now classic experiments with iodine at Hanford, with strontium and plutonium at ANL, Hanford, and the University of Rochester, with cesium at Argonne and Berkeley, with tritium at Hanford and Brookhaven, and effects in the fetal and juvenile mammal, also at Hanford. Inhalation of radioactive gases is reviewed historically in chapter 9 and in more detail in chapter 10.

The monumental long-term experiments with strontium, the actinides, and radium are reviewed in depth in chapter 8 and the story of the radium dial painters in chapter 1.

Comparable long-term experiments, but tied more specifically to the problems of weapons fallout, done at the University of California at Davis (ingestion) and at the Inhalation Toxicology Research Institute, Lovelace Foundation (inhalation), are described briefly^(a) also in chapter 8, but in much more detail in chapters 9 and 13 (Lovelace) and in chapter 13 (Davis). Also, much work leading toward understanding of biological mechanisms is reviewed, especially in chapters 13 and 21.

The reader with limited time and interests primarily in the science as contrasted to phenomenological aspects, might well concentrate on chapters 8 and 13. Conversely, the reader interested primarily in the events, behavior of radioisotopes and their effects may wish to concentrate on chapters 11, 12, and 15, with a light reading of chapter 8.

4. Standards

A full chapter (chapter 16) is devoted to standards for exposure to radiation, with emphasis on radioisotopes and how biomedical research data undergirded the development of standards. Development of population standards is included, and there is some discussion of specific exposure standards for fallout, and emergency exposure levels in general, both there and in chapter 12. The general history of radiation protection standards is given largely by references, since the subject is covered well elsewhere.

The influence of findings regarding the environmental transfer of radionuclides to food and water on the setting and application of standards for nuclear reactors is given special attention in chapter 15.

(a) Several experiments with cesium are included in this work.

G. Is Chernobyl the End of Nuclear Power?(a)

Only time can tell. Reactions have been violent in some parts of the world, and the implications have been made, especially in the United States, that we have an uncontrollable monster in our midst, and it should be destroyed. By contrast, those who really depend on nuclear energy for power are going about business as usual (IAEA 1986). The undamaged reactors at Chernobyl are already back in operation after extensive decontamination. Perhaps no better example is needed of the application of the risk-benefit equation. Somewhere, sometime the best balanced procedures for meeting the power needs of a shrinking world will emerge. Meanwhile, we can only conclude that the biomedical problems of nuclear power (Note: not nuclear war) are probably no more pressing than those, for example, of general chemical contamination, of epidemic diseases, such as AIDS and malaria, and the control of hunger and famine. Only nuclear war can dominate all of these.

NOTE 1

Subject index from Wasserman and Comar (1961): Annotated bibliography of strontium and calcium metabolism in man and animals. This indicates the range of topics under investigation even at that early date.

SUBJECT INDEX

	Item		Item
Absorption, amino acids and Ca, Sr.	141	Alkaline earths (see also Barium, Calcium, Strontium).	
of calcium.	100, 101, 106, 126, 144, 158, 168, 207, 212, 214, 217, 241, 254, 872, 874, 877, 878, 879	amino acid complexes of.	284, 286
of calcium, by fish.	107, 125, 129, 220, 239	biochemistry of.	29
by man.	107, 109, 110, 113, 119, 126	biological mechanisms.	360
by rats.	112, 117, 118, 120, 126, 141, 142	in bone.	160, 998
of calcium and Sr.	100, 101, 106, 126	and calcification.	416
of fission products.	114, 115, 123, 124	and chelation.	188
of phosphorus.	131, 135, 136, 137	complexes.	287, 288
of phosphorus supplements.	153, 154, 155, 156, 157	Alkaline phosphatase, in calcification.	419
of plutonium.	115	and corticoids.	721, 734
of strontium.	100, 101, 106, 126, 231, 241, 251, 252, 816	and radiation.	1028
of strontium, by chick.	130, 142	in rickets.	594, 608, 640, 617
by fish.	248	Alkalosis, plasma Ca in.	282
by rats.	111, 121, 122, 126, 130, 141	Alpha emitters, in bone.	1007
by skin.	180, 190, 191, 192		1033, 1043, 1055, 1056, 1057
of tricalcium phosphate.	144	Amino acids, and calcium, Sr absorption.	284
of vitamin D and Ca.	118, 618, 633, 635, 639, 641, 612, 643, 644, 645, 905	complexes of.	284
Acidosis, plasma Ca in.	23	incorporation into milk proteins.	800
Actinide elements, metabolism.	282	Ammonium chloride, and strontium* removal.	1084
Activation analysis, for strontium and Ra.	220, 485	Analysis, for barium.	1131, 1133, 1135, 1150, 1160
for trace elements.	1125, 1135	of biological fluids.	1127, 1128, 1155, 1157
Adenosine phosphate, calcium and Mg complex.	276	of bone.	1124, 1126, 1132, 1148, 1159
complexes with.	287, 288	for calcium.	1121, 1124, 1127, 1128, 1130, 1131, 1132, 1134, 1138, 1139, 1140, 1143, 1147, 1148, 1149, 1150, 1151, 1155, 1156, 1157, 1158, 1161
Adenosinediphosphate, calcium complexes.	413	for endogenous phosphorus.	1142
Adenosinetriphosphate, in calcification.	438	of excreta.	1136
calcium complexes.	413	of fallout.	909, 910, 911, 912
in cartilage.	409, 412, 438	for fission products.	1145, 1151
Adrenal steroids, and calcium.	727, 736	of food.	1126, 1151, 1159
Adrenalectomy, and strontium.	764	of kidney decalcification.	1121
Adsorption. (See Bone, calcium exchange in.)		for magnesium.	1127, 1130, 1137, 1138, 1151, 1156, 1161
Aerosols, of fission products.	958, 1015	of milk.	1126, 1138, 1159
Age, and bone composition.	466	for potassium.	1130, 1140, 1148
and bone growth.	833, 834, 835	of rocks.	1150
and calcium metabolism.	213, 291, 296, 297, 553, 827, 828, 829, 830, 831, 832, 836	of serum.	1130, 1139, 1147, 1156, 1158
and calcium requirement.	558	for sodium.	1121, 1130, 1140, 1148
and metabolism of fission products.	825	of soils.	1144, 1159
and phosphorus metabolism.	824	of spinal fluid.	1161
and rickets.	830	for strontium.	1123, 1126, 1129, 1131, 1132, 1133, 1134, 1135, 1136, 1141, 1144, 1145, 1146, 1150, 1157, 1159, 1160
and sodium metabolism.	820	of tissues.	1122
and strontium metabolism.	225, 228	of urine.	1153, 1145
Agents, for radiolotope removal.	1084, 1094, 1095	of water.	1123, 1129, 1141, 1145
Aging, and diet.	834	of whole body.	1116
Agriculture, radiolotopes in.	11, 32, 51		
Alizarin, use in bone studies.	370

removal from body.....	1082, 1083, 1085, 1091, 1100, 1101, 1107, 1108, 1110, 1111	radiation effects on.....	528
toxicity of.....	959, 974, 982, 1034, 1039, 1051, 1067	tissue composition.....	518
Fixation, of calcium in bone.....	383, 385, 387, 389, 391, 392, 393, 394, 395, 396, 397, 398, 401, 406	vitamin D effect on.....	480, 616
of lead in bone.....	389	Histochemistry, of bone.....	482
Fluorine, on bone.....	837, 838, 839, 840, 841, 842, 847	of calcification.....	426
bone histology.....	842	fluorine in bone.....	839
bone matrix.....	838, 839	of irradiated bone.....	970
in calcification.....	843, 844	of parathyroids.....	680b
and calcium metabolism.....	845, 846	of vitamin D.....	583
effect on calcification.....	441	Histogenesis, of bone.....	415
and fracture healing.....	433	Histology (see also Pathology)	
and lathyrisms.....	847	and fluorine.....	842
and phosphorus metabolism.....	845	of radiation.....	965, 994, 995
and teeth.....	515, 838, 840, 841, 844	of strontium rickets.....	459
Folic acid, against strontium leukemia.....	667	of teeth.....	499
Food, analysis of.....	1126, 1154, 1159	in vitamin D studies.....	615
calcium content.....	569	Hormone studies, in dog.....	745
Food chain, fission products in.....	940	in mouse.....	730
strontium in.....	146	in rat.....	721, 722, 727, 729, 734, 739, 740, 741, 742, 744, 748
Foods, cesium in.....	933	in sheep.....	737
potassium* in.....	933	Hormones, on blood minerals.....	689
Foodstuffs, phytic acid in.....	866	and bone growth.....	673, 677, 703
Formation constants, of complexes.....	283, 288	and bone metabolism.....	746
Fossils, calcium exchange in.....	390	and calcification.....	418
strontium content.....	464, 476	and calcium fixation.....	677
Fracture, bone studies.....	325	and fat.....	738
Fracture healing (see also Bone healing)		in man.....	728, 731, 733, 738
calcium uptake in.....	345, 357, 369, 374	and metals.....	675
fluorine and.....	433	and minerals.....	675
phosphorus in.....	388	parathyroid.....	688
phosphorus uptake in.....	347, 374	and protein.....	738, 747
plutonium uptake in.....	381	tumor studies.....	678
strontium and.....	433	Horse, calcium in bone of.....	466
strontium uptake in.....	381	calcium studies in.....	891
sulfur uptake in.....	369	phosphorus in bone of.....	460
and vitamin A.....	599	Hydration shell. (See Surface chemistry.)	
and vitamin D.....	599	Hypercalcemia.....	373
yttrium uptake in.....	369, 381	Hypophyseal hormone, assay for.....	760
Frog, strontium* in.....	981	Hypophysectomy, and phosphorus.....	765
Function, of metals.....	74	and strontium.....	764
Gargoylism, and calcium.....	168, 208	Hypophysis, bone and protein.....	759
Gastrectomy, and mineral balance.....	894	and calcium metabolism.....	758
Gastric acidity, and radiation.....	881	Inhalation, of fission products.....	958, 1015
Gastric secretion, and vitamin D.....	626	of strontium*.....	876
Gland extracts, and bone growth.....	897, 898	Inhibition, of calcification.....	420, 441, 442, 444, 884
Glucose, in the udder.....	802	Injury. (See Toxicity.)	
Glycerophosphate, in teeth.....	504	Insects, barium content.....	498
Glycogen, and cartilage.....	895	calcium content.....	186
Glycolysis, in calcification.....	439	radiolabel effects on.....	987
in cartilage growth.....	414, 429, 430, 434	strontium in.....	179, 498
Goat, calcium in milk.....	769	strontium* effects.....	1002
lactation studies in.....	780, 812, 813, 817	Internal emitters (see also Radiolabels)	
parathyroids.....	707	permissible levels.....	1013
strontium in.....	252, 816	Iodine ¹³¹ , in cattle and human thyroid.....	916
strontium* studies in.....	969, 1020	in milk.....	916
Grafts, of bone.....	316, 317, 334	survey values.....	931
Graham's salt, and strontium.....	853	Ion exchange (see also Bone, calcium exchange in)	
Grazing animals, and fallout.....	954	for radiolabel removal.....	1100, 1101
Great Britain, fallout in.....	913	Ion exchange resins, and minerals.....	859
Growth hormone, and bone.....	766	Iron, effect of bone meal on.....	540, 547, 549
in rats.....	600, 601	intake in children.....	539
Growth hormone, and strontium.....	761	Isotope dilution.....	1093
and sulfur.....	762	of phosphorus.....	579
Guinea pig, fission product studies.....	1082	of strontium.....	545, 552, 555, 571, 582
strontium in.....	609	Kidney (see also Renal)	
strontium and Ca in.....	75, 81	analysis of, calcium in.....	238
thyroid studies in.....	752a	decalcification.....	1121
vitamin C studies.....	670	Lactation, and bone.....	540, 541
Gypsum, as calcium source.....	849	and calcium.....	377, 773, 778, 795, 796, 797, 810, 812, 815, 817, 818, 819
Hair, calcium and P in.....	143	fission products in.....	680, 776, 790, 793, 794
Hamster, calcium requirement.....	558	and minerals.....	794, 798
teeth mineralization.....	499	and parathyroid.....	701, 718
Handbook, of biology.....	67	and phosphorus.....	774, 791, 819
Haversian systems (see also Bone)		physiology of.....	809
by calcium.....	365	Lactoglobulin, calcium binding of.....	908
Hazard, from strontium*.....	932, 933, 934, 935, 937, 951, 952	Lactose, and calcium, Sr absorption.....	141

Rabbit, blood studies in	888	composition	596
bone studies in	673, 897	deposition	160
calcification in	427	growth	343, 344, 345, 346, 347, 376, 377, 378, 382, 550, 576, 614, 645, 654, 663
calcium absorption by	126	histochemistry	482
calcium exchange in	383, 385	Rat, bone, histology	580
calcium studies in	295, 296, 297, 890	studies	763, 764, 765, 889, 873
calcium supplements	145, 158	boron in	175
Haversian systems in	365	calcium, in bone of	311, 312, 320
lactation studies in	819	bone exchange	387
lactin studies in	819	metabolism	102, 107, 209, 213, 256, 265, 291, 544, 553, 554, 561, 563, 569, 773, 783, 907, 1080
parathyroid	682, 695	and phosphorus supplements	144, 149, 150, 151, 551, 563, 554
phosphorus in bone of	318	requirement	558
pregnancy studies	819	calcult in	575
radium in	205	cories in	502
strontium in	204, 226, 228, 231, 251, 315	cartilage studies in	409, 410
strontium and Ca in	75, 91, 106	complexing agents in	853, 854, 859, 860, 863
strontium ⁹⁰ toxicity	961, 962	dietary studies in	849, 808, 870, 873, 874, 882, 885, 903, 904, 905
strontium ⁹⁰ studies in	1004, 1005	EDTA studies in	1112
yttrium in	228	effect of low calcium diet	538, 556, 569
Radiation, and alkaline phosphatase	1028	fission-product studies in	180, 181, 218, 227, 308, 972, 1015
biological effects	887, 1065	fluorine studies in	840, 841, 844, 845, 846, 847
bone effects	1023, 1027, 1033, 1034, 1036, 1038, 1039, 1041, 1055, 1056, 1057, 1059, 1063	fracture healing	599
Radiation, dosimetry	26, 53	and growth hormone	600, 601
effects of	1, 5, 39, 45, 53, 57, 66, 70, 828, 991, 1007	hormone studies	721, 722, 727, 729, 734, 739, 740, 741, 742, 744, 748
and gastric acidity	881	inhalation studies	958, 1015
histology of	965, 994, 995	iron metabolism in	546, 547, 549
and leukemia	946	lactation studies in	786, 787, 788
and liver function	1064	lead removal from	578
in medicine	3, 33	mineral studies in	901
of oral tissues	1037	parathyroid	680c, 681b, 681c, 685, 698, 699, 701, 706, 710, 711, 712, 713, 714, 715, 716, 717, 719
on phosphorus metabolism	1025, 1026	phosphorus absorption	131
protection from	966	phosphorus in bone of	301, 326, 428a, 428b
on sperm	1068	phosphorus metabolism	530, 554
and splenectomy	988	plutonium in	227
teeth effects	1006	radioisotope studies in	1011, 1037, 1049
Radiation biology, general	1, 30, 45, 53, 57, 66, 70	radium in	341
Radioactivation analysis. (See Activation analysis.)		radium toxicity	996
Radioactivity (see also specific radioisotope)		strontium absorption	111, 121, 122, 126, 130, 141
and fisheries	950	absorption in skin	180, 190, 191, 192
in man	915, 933, 938, 955	in bone	299, 302, 303, 329
in milk	806	and calcium in	75, 78, 81, 82, 83, 85, 88, 91, 92, 105, 106
and oceanography	950	metabolism in	175, 204, 225, 515, 552, 555, 570, 571, 582, 620, 1075, 1080, 1117
in thyroid	931	rickets in	450, 451, 453, 454, 455
Radioautography. (See Autoradiography.)		strontium ⁹⁰ toxicity	961, 962, 1040
Radiochemistry, general	4, 24, 25, 37	strontium ⁹⁰ toxicity	960, 994, 995, 1008, 1009, 1036
Radiochemistry, of oral tissues	971	thyroid studies in	781, 754, 766
Radiochemistry	19, 64	tooth studies in	422, 499, 503, 504, 508
Radiochemicals, of fission products	285	vitamin A studies	669
Radioisotopes (see also specific radioisotope)			
bioassay	1014		
in biology and agriculture	11, 24, 25, 32, 37, 51		
in bone	304, 310, 323, 325, 331, 332, 374, 377, 379, 1012		
for bone-growth studies	356, 362		
and bone strength	364		
dosimetry of	997		
and EDTA	1081		
effect on insects	987		
exchange into bone	397		

*Radioactive.

vitamin C studies.....	Item 670	Strength, of bone.....	Item 484
vitamin D effects.....	585	Strontium, absorption.....	111
588, 600, 601, 602, 604, 605, 607, 610, 614, 620, 622, 623, 626, 628, 633, 635, 645.		activation analysis.....	121, 122, 126, 130, 141, 142, 816
Recrystallization. (See Bone, calcium exchange in.)		and adrenalectomy.....	220
Region, effect on Sr content of human bones.....	492	amino acids and absorption.....	704
Relative biological efficiency, of internal emitters.....	982	and ammonium chloride.....	141
of X- and beta rays.....	990	analysis for.....	1084
Remineralization. (See Calcification.)		1126, 1129, 1131, 1132, 1133, 1134, 1135, 1136, 1141, 1144, 1145, 1146, 1150, 1157, 1159, 1160	914, 1123, 1136, 1146
Removal, of calcium* from body.....	1090, 1117, 1119	availability of.....	146
of fission products.....	1082, 1083, 1085, 1094, 1100, 1101, 1107, 1108, 1110, 1111	Strontium, and BAL.....	1091
of strontium* from body.....	556, 1084, 1097, 1098, 1101, 1114, 1115, 1117	in bone.....	17, 89, 90, 226, 299, 302, 303, 305, 306, 313, 314, 315, 319, 320, 321, 324, 327, 329, 335, 356, 363, 402, 475, 485, 492
Renal excretion, of calcium.....	209, 211, 216, 234, 237, 238, 241, 242, 244, 247, 255, 258, 852	composition.....	1016
of magnesium.....	852	fracture.....	989
Renal function, calcium effects on.....	247, 258	graft studies.....	371
and EDTA.....	1109	growth.....	911
parathyroid and.....	716	pathology.....	380
strontium effects on.....	215, 233, 211	in calcification.....	991, 995, 1008, 1009, 1048, 1052, 1054
Repair, of bone.....	483	and calcium, in bile.....	412, 414
Requirements, for calcium.....	119, 143, 558	comparison.....	75, 77, 78, 80, 81, 82, 83, 81, 85, 88, 91, 93, 98, 100, 101, 103, 106, 516
for phosphorus.....	143, 153, 154, 155, 156, 157	excretion effects.....	243
Resins, mineral removal by.....	1072, 1101	in fetus.....	85, 106
Riboflavin, and bone growth.....	619	in fish.....	94, 95, 96, 108
Rice, and calcification.....	633	function.....	452
Rickets, and age.....	836	in shells.....	103
alkaline phosphatase in.....	591, 608, 646, 617	supplements.....	456
blood minerals.....	591, 646, 647, 657	transport.....	97
and bone growth.....	350	Strontium, regional effects on bone content of.....	492
calcification in.....	438	removal, from body.....	556, 1084, 1097, 1098, 1101, 1114, 1115, 1117
and calcium.....	605a	from milk.....	1105
and calcium fate.....	213	from water.....	1106
and dietary citrate.....	854, 860	renal function.....	215, 233, 241, 243
effect, of calciferol.....	595	and rickets.....	450, 451, 453, 454, 455, 457, 458, 459, 567
of phosphorus in bone.....	428a, 428b	in sea water.....	481
of strontium.....	449	in shells.....	463, 481, 491
on strontium.....	225	skin absorption of.....	189, 190, 191, 192
fixation of strontium in.....	565	stable.....	80, 81, 104, 320, 321, 1089
and phosphatase.....	638	surveys.....	913, 917, 918, 919, 920, 921b, 922, 923, 924, 925, 926, 927
phosphorus metabolism in.....	596, 613, 634, 640, 646, 647, 657, 659, 660	in teeth.....	509
radioisotopes in.....	652	therapy with.....	1060, 1061
resistant.....	621, 657, 659	toxicity of.....	960, 961, 962, 973, 976, 978, 979, 980, 982, 984, 988, 990, 992, 994, 995, 999, 1001, 1003, 1005, 1008, 1009, 1020, 1024, 1029, 1030, 1032, 1035, 1036, 1041, 1048, 1049, 1053, 1056
by strontium.....	450, 451, 453, 454, 455, 457, 458, 567	transport.....	122, 139, 142
strontium and Ca in.....	620	vitamin B ₁₂ effect.....	587
Rocks, analysis of.....	1150	vitamin D.....	620
Roughage, antivitamin D.....	666	in worms.....	264
Saliva, in teeth metabolism.....	500	and zirconium.....	804
Salivary glands, calcium in.....	172, 265	Structure, of bone.....	36, 49, 56, 61, 68, 73, 359, 384, 399, 493, 495
and thyroid.....	756, 757	of bone mineral.....	399, 402, 403, 404
Sarcoidosis, bone in.....	896	of cartilage.....	354
Sarcoma. (See Toxicity.)		Sugars, and calcium absorption.....	872, 874, 877, 878, 879
Scurvy, trace elements in.....	670	Sulfur, in bone.....	837
Sea water, strontium content.....	481	bone exchange of.....	397
Serum (see also Blood)		in bone-growth studies.....	366, 367, 368
analysis of.....	1130, 1139, 1147, 1150, 1158	in cartilage.....	336, 762
Serum albumin, mineral complexes with.....	200	effect of vitamin D.....	592, 610, 612
Sleep, blood composition.....	478	and estrogens.....	729
bone density in.....	472	in fracture healing.....	369
effect of calcium on bones.....	540, 541	and growth hormone.....	762
hormone studies.....	737	into milk.....	800
lactation studies on.....	823	and parathyroids.....	681b
Shell organisms, strontium and Ca in.....	103	Sulfur ³⁵ , bone effects of.....	1010
Shells, calcium in.....	224, 448	Sunshine project.....	941, 953
calcium and P in.....	163	Supplements, of calcium and P.....	143, 150, 158
strontium content.....	463, 481, 491	calcium, by rectum.....	145
X-ray diffraction of.....	481	Surface chemistry, of bone.....	402, 403, 404, 405, 407, 408
Sinlondectomy, and calcium metabolism.....	752b, 755, 766	Surfaces, in bone metabolism.....	402, 403, 404, 405, 407, 408
Skeleton. (See Bone.)		Surveys, for cesium.....	913, 933
Skin, calcium in.....	162	for fallout.....	909, 910, 911, 912, 913, 917, 918, 919, 920, 921a, 921b, 922, 923, 924, 925, 926, 927, 929, 930
strontium absorption by.....	189, 190, 191, 192	for strontium.....	913, 917, 918, 919, 920, 921a, 921b, 922, 923, 924, 925, 926, 927
transport in.....	201, 202, 203	Synergism, of radioisotope effect.....	986, 1011
Sodium, and age.....	826	Tantalum, toxicity of.....	973
analysis for.....	1124, 1130, 1140, 1148	Techniques, autoradiography.....	9
in blood.....	461	of peritoneal lavage.....	714
bone exchange of.....	386	in radiochemistry.....	4, 11, 24, 25, 37
calcium antagonism.....	279	radioisotope.....	11, 24, 25, 37
Soft tissues, calcium in.....	162		
Soils, analysis of.....	1144, 1159		
strontium and Ca in.....	61		
Solubility, of bone.....	480		
Somatotropic hormone. (See Growth hormone.)			
Sperm, radiation effects on.....	1068		
Spinal fluid, analysis of.....	1161		
Spleen, and calcium metabolism.....	680a		
Splenectomy, and radiation effects.....	988		
Stability, of complexes.....	283, 284, 286, 287, 288		

*Radioactive.

Appendix A

The Interviews

A very important feature in the preparation of this book was the opportunity to meet personally with over one hundred of the investigators who played a part in the history described. Some are "patriarchs" whose work forms the basis for entire areas of the research described, who have (or had) been active for fifty years or more, and who did much to shape the entire field we are calling radioisotope toxicology. Others are key figures of the second generation who shaped the major programs of the "Golden Era" described in chapter 8. Still others are specialists in certain aspects whose contributions made possible the exploration of avenues that might otherwise have remained undeveloped. A few are relatively recent arrivals, who have a grasp nonetheless of the history behind them and who have assumed responsibility for the future.

Unfortunately, a few of those interviewed in the early phases of preparation are no longer with us. Perhaps we need no more forceful indication that it was high time this history was written.

Despite the effort expended on interviews, this book cannot and should not be termed an oral history. The results of the conversations were always used to confirm and extend, or to add anecdotal flavor to the unfolding written stories of the research programs. The reports and published literature formed the basic structure that the interview results then fleshed out and made more personal, frequently more specific, even more correct. Thus, the book is a combination of oral history and conventional digging into the literature. Both were enjoyable and revealing, but the personal interviews were especially stimulating and pleasant.

Unfortunately, as the project grew in size, it was necessary to eschew information gained in the interviews, as it was necessary to discard parts of the written record. It is hoped that some other opportunity will be presented to air these items, particularly anecdotal material.

The author is most grateful to the many friends and colleagues who extended time and talent, sometimes more than once, and sometimes for many hours at a stretch, to recall details of what was done, how it was done, and the milieu existing at the time it was done. Some of the interviews lasted less than an hour; a few required the better part of two days. Obviously, they concentrated on each individual's personal research interests, but sometimes much broader topics occupied the stage. Sometimes those interviewed had been asked to read,

prior to the interview, a draft copy of a chapter pertinent to their experience. The discussion was then built upon a critique of something already written. Most often, however, the interview was an occasion for sheer recall and commentary.

A majority of the interviews were taped and later transcribed. Both are being readied for deposit in a suitable repository after they have been edited. Unfortunately, in the early efforts, the author used tapes that did not hold up well, and the record of those interviews must be limited to notes.

In the listing that follows, the interviews are arranged alphabetically by last name. Also, the individual's base of operations and the position or field of operation at the time of the interview or prior to retirement are given. For the reader's convenience, there is also an indication of the principal subject matter discussed. Most of the discussions took place at the interviewee's home base, and sometimes they became a group affair as colleagues joined in. Other interviews took place at national scientific meetings, from which the individual was willing to break away for an hour or so. Still others were at the site of the individual's place of retirement.

There is no doubt that these person-to-person encounters contributed importantly to the text. Sometimes their contribution is obvious and direct and can be referenced formally. In other cases, indeed the majority, the interview contributed primarily to the general flavor of what was going on, or it confirmed or modified the written record. These could seldom be cited directly. Hence, the need for this Appendix.

Financial support for travel and other expenses came from the U.S. Department of Energy through Pacific Northwest Laboratory and is acknowledged with gratitude.

Note: Principal subject matter follows each entry.

Name and Position	Institution	Date(s)
Agnew, Harold , President formerly Director of Los Alamos Scientific Laboratory Work at Met Lab and at research.	GA Technology, La Jolla, CA (formerly General Atomics) Los Alamos Los Alamos during World War II, also early postwar	May 2, 1980
Alpen, Edward Director of Donner Laboratory Naval Radiological Defense Laboratory.	University of California at Berkeley	May 15, 1978, plus discussion in April 1984
Anders, Roger Archivist History of AEC.	AEC, ERDA, DOE Headquarters Germantown.	March 16, 1979
Andrews, Howard L. Professor of Radiation Biology & Biophysics USPHS (retired in Jamestown, R.I.) Instrumentation, weapons tests, general.	University of Rochester National Institutes of Health	September 1980, and many letters since

Name and Position	Institution	Date(s)
Auerbach, Stanley Director, Radioecology Div. Growth and development of radioecology program at Oak Ridge.	Oak Ridge National Laboratory	April 19, 1979
Auxier, John , Head, Health and Safety Research. Oak Ridge programs	Oak Ridge National Laboratory Applied Science Laboratories, Oak Ridge	April 13, 1979
Bair, William J. , Manager, Biomedical and Environmental Research Program. Contract officer for this book. Manager, Life Sciences Center All aspects, particular emphasis on inhalation toxicology:	Battelle, Pacific Northwest Laboratories	June 12, 1979, plus numerous consultations
Bale, William F. , Professor of Radiation Biology and Biophysics. (deceased) Nuclear medicine, radioactive antibodies, research at Rochester during World War II, his work at Georgia Tech since "retirement."	University of Rochester Medical Center Georgia Tech	November 5-6, 1979
Ballou, John Staff Scientist Research at Hanford and Battelle-Northwest.	Battelle, Pacific Northwest Laboratories	June 5, 1979
Baum, John Safety and Environmental Protection Division Marshallese dosimetry.	Brookhaven National Laboratory	September 17, 1982
Bennett, Robert Professor of Radiology History of nuclear medicine and his research.	University of California Los Angeles, Medical Center	February 8, 1979, also 1981, and letters
Bernard, Robert Staff Scientist Uranium research, metabolic models.	Oak Ridge National Laboratory	April 17, 1979
Bethard, William F. Staff Physician His role at Chicago during the 1940s. Biomedical work at GA.	GA Technology, La Jolla, CA (formerly General Atomics)	July 17, 1978
Boecker, Bruce Assistant Director Thorium, field tests, bioassay, metabolic models.	Inhalation Toxicology Research Institute, Albuquerque	September 26, 1981
Bond, Victor Director, Medical Division Medical dosimetry, his experiences with the Marshallese, cellular aspects of nuclear medicine, cellular models.	Brookhaven National Laboratory	September 16, 1982
Bonham, Kelshaw Professor in College of Fisheries (retired) The University of Washington Fisheries program. Joint interview with Larson and Welander.	University of Washington	June 1, 1979

Name and Position	Institution	Date(s)
Brucer, Marshall Medical Director (retired in Tucson, Arizona) The Oak Ridge medical program, history of nuclear medicine, fallout.	Oak Ridge Institute of Nuclear Studies	December 5, 1979
Brues, Austin Scientific Staff, Institute for Human Radiobiology. Former Director, Biology Division Radium cases, program at Argonne, radium pharmacokinetics.	Argonne National Laboratory	September 8, 1978, October 8, 1981, and several follow-up discussions and letters
Bruner, David, Staff, Division of Biology and Medi- cine, and subsequent entities Entire program. Special emphasis on inhalation problems. Interviewed in Florida where he is now retired.	AEC, ERDA, DOE	November 14, 15, 1979
Burr, William, Director Division of Biological and Environmental Research His view of the internal emitter program in all three agencies, especially AEC history.	AEC, ERDA, DOE Headquarters Germantown Now at Oak Ridge Associated Universities and CARL	March 13, 1979, and subsequent follow-ups
Bustad, Leo, Dean, College of Veterinary Medicine formerly Director of AEC program formerly Staff Scientist General history of the Hanford programs, particularly large animal work plus corollaries from his other experiences, sheep exposures at NTS.	Washington State University University of California, Davis Hanford Biology Operations	September 25, 1981, and follow-up letters
Carsten, Arland Medical Department Tritium, nuclear medicine.	Brookhaven National Laboratory	July 1982, September 1982
Carter, Melvin, Professor, Nuclear Engineering The PHS program at Southwestern Radiological Health Laboratory, at NTS, and current work at Georgia Tech.	Georgia Institute of Technology Formerly U.S. Public Health Service, several laboratories	April 10, 1979, and several subsequent letters
Carter, Nicholas Division of Biological and Environmental Research General	DOE Headquarters, Germantown	March 13, 1979
Casarett, George Professor of Radiation Biology and Biophysics and of Radiology Pathology work in MED days, polonium experiments at Rochester, general.	University of Rochester Medical Center	May 28, 1978, May 15, 1979

Name and Position	Institution	Date(s)
Claus, Walter Special Assistant, Division of Biology and Medicine All aspects of program, especially the large animal experiments. Interviewed in Florida where he is now retired.	AEC and ERDA Headquarters Germantown	November 16, 1979, and several sub- sequent visits
Cloutier, Roger Scientist, Medical Division Dosimetry, MIRD, nuclear medicine, epidemiology.	Oak Ridge Institute of Nuclear Studies	July 12, 1979
Cohn, Stanton Medical Department NRDL, Marshallese, current work at Brookhaven in whole-body counting and problems of bone.	Brookhaven National Laboratory	September 16, 1982
Collins, Donald President Instrumentation experience in MED and weapons tests.	Don L. Collins and Associates, Glendale, CA	October 13, 1978
Cowan, Frederick Director, Health Physics (retired) WASH 740, BNL research, both health physics and environmental. Interviewed at scientific meeting and at his home in Florida.	Brookhaven National Laboratory	July 10, 1979, April 1984
Cronkite, Eugene Medical Department Marshallese, NRDL, nuclear medicine.	Brookhaven National Laboratory	September 15, 1982
Cross, Fredrick Scientist Radon and uranium miners, animal work with radon. Joint interview with Ray Palmer.	Battelle, Pacific Northwest Laboratories	June 4, 1979, and sev- eral subsequent con- versations and letters
Deal, Joe Fallout problems.	DOE Headquarters Germantown	March 16, 1979, March 31, 1980
Donaldson, Lauren Professor, School of Fisheries Fisheries program at University of Washington, Pacific studies, marine ecology.	University of Washington	May 31, 1979, October 7, 1983
Dounce, Alexander Professor of Biochemistry (emeritus) Uranium work during MED days.	University of Rochester Medical Center	June 19, 1978
Drew, Robert Inhalation Facility Inhalation toxicology.	Brookhaven National Laboratory	September 15, 1982
Durbin, Patricia , Scientist, Lawrence Radiation Laboratory MED work at Berkeley with J. Hamilton, laboratory research on actinides, bone, uranium, standards. First interview in San Diego, second at Berkeley.	University of California, Berkeley	October 31, 1979, October 1980, and subsequent letters

Name and Position	Institution	Date(s)
Eisenbud, Merrill Professor, Institute of Environmental Medicine Work of HASL, fallout, Sterling Forest, Brazil, work at NYU.	New York University Now at Chapel Hill, NC	July 9, 1979, and subsequent discussions
Evans, Robley Professor of Physics (retired) Radium story, radon and uranium miners' standards. Also the Institute for Human Radiobiology at Argonne. Interviews at Scottsdale, Arizona, where Dr. Evans has retired.	Massachusetts Institute of Technology	April 16, 26, 1978, and several subse- quent letters
Facer, Gordon Formerly classified literature.	U.S. Department of Energy	April 7, 1980
Fairchild, Ralph, and Sam Packer New developments in nuclear medicine.	Brookhaven National Laboratory	September 6, 1982
Feldman, Isaac Professor of Radiation Biology and Biophysics Uranium and polonium chemistry.	University of Rochester Medical Center	June 6, 1978
Fink, Kay Administration The polonium experiments at Rochester during World War II.	University of California, Los Angeles	February 8, 1979
Finkel, Asher Occupational Medicine (retired) The Argonne radium studies, chapter critiques.	American Medical Association Formerly Argonne National Laboratory.	October 9, 1981, with subsequent letters
Finkel, Miriam Biology Division (retired) The Met. Lab experiments on fission products and actinides. Postwar long-term experiments.	Argonne National Laboratory	September 6, 1978, October 9, 1981, with subsequent letters
Ford, Mary Internal emitter dosimetry.	Oak Ridge National Laboratory	April 17, 1979
Foreman, Harry, Professor Therapy for deposited radionuclides. Interview in San Diego.	University of Minnesota	1978
Foster, Richard Environmental Sciences Very broad. Early work at University of Washington and Hanford, especially aquatic biology. Pacific tests, whole-body counts, general environmental studies.	Battelle, Pacific Northwest Laboratories	June 11, 1979
Friedell, Hymer Professor of Radiology (retired) His book on history of Manhattan Project, old reports, work at WRU.	Western Reserve University	May 15, 1978, May 27, 1981

Name and Position	Institution	Date(s)
Goldman, Marvin Director, Laboratory for Energy Related Health Research General, emphasis on bone and experience at tests program at Laboratory, Chernobyl.	University of California, Davis	December 5, 1980, May 1983, and several informal follow-ups
Hacker, Bart Author of book in preparation on radiation protection at the weapons tests His book. Interview in San Diego.	Reynolds Electric and Engineering Co., Las Vegas	September 19, 1979
Hackett, P. L. and B. J. McClanahan Their programs.	Battelle, Pacific Northwest Laboratories	June 5, 1979
Haggerty, James Radium, chapter. Joint interview with C. W. Shilling and W. Lotz in Washington, June 1978.	American Red Cross, Washington Headquarters Formerly AEC	April 1978
Hansard, Sam History of the UT-AEC farm, and CARL programs.	Cooperative Animal Research Laboratory, Oak Ridge (formerly UT-AEC Experimental Farm)	April 18, 1979
Hasterlik, Robert The Argonne radium studies.	La Jolla Cancer Research Foundation, La Jolla, CA Formerly Argonne	April 28, 1980
Hempelmann, Louis Professor of Experimental Radiobiology (retired) The radium cases. The Los Alamos plutonium workers.	University of Rochester Medical Center	June 6, 1978, September 1981
Hewlett, Richard Historian (retired) Pertinent history of AEC.	AEC, ERDA, and DOE Headquarters, Washington.	March 15, 1979
Hodge, Harold Professor of Pharmacology and Toxicology (retired) Uranium research and inhalation toxicology, chapter reviews.	University of Rochester Medical Center University of California, San Francisco	October 25, 1980, and subsequent visits in California
Holaday, Duncan (retired) Uranium miner saga.	U.S. Public Health Service	July 9, 1979

Name and Position	Institution	Date(s)
Hull, Andrew Safety and Environmental Protection Division Radiation protection, environment studies.	Brookhaven National Laboratory	September 17, 1982
Hursh, John Professor of Radiation Biology and Biophysics (emeritus) Broad review of instrumentation, radium, polonium, and radon research.	University of Rochester Medical Center	May 31, 1978
Jee, Webster Professor, Radiobiology Program Utah programs, fallout, bone.	University of Utah	January 18, 1980
Jordan, Harry Work at NTS, particularly Project 56 and other plutonium safety tests.	Los Alamos National Laboratory	September 22, 1981
Kathren, Ronald Historians' views and experiences.	Battelle, Pacific Northwest Laboratories	June 5, 1979, and many subsequent discussions
Kornberg, Harry Manager (deceased) History of the Hanford biology effort and his experiences. General consideration of fallout and related problems, work with tritium.	Bonneville Power Administration and EPRI Formerly Hanford Biology Division	September 1, 2, 1982, with subsequent letters
Kreager, William (retired) NRDL.	U.S. Nuclear Regulatory Commission	December 6, 1979
Larson, Kermit UCLA work at NTS. Joint interview with Welander and Bonham.	Damson Moore, Seattle, WA	June 1, 1979
Lessard, Edward Safety and Environmental Protection Division Dosimetry of Marshalllese. Joint interview with Charles Meinhold part of the time.	Brookhaven National Laboratory	September 17, 1982
Lotz, William Inhalation Toxicology Programs of AEC. Also joint interview with Drs. Shilling and Haggerty, June 1978.	Electric Power Research Institute branch in Washington Formerly AEC Division of Biology and Medicine	March 15, 1979
Marks, Sidney Associate Manager, Biomedical and Environmental Research (retired) Broad review.	Battelle, Pacific Northwest Laboratories	June 11, 1979
Mays, Charles Professor, Radiation Biology Program Therapy for deposited radionuclides, the Utah experiments, Thorotrast.	University of Utah	January 18, 1980

Name and Position	Institution	Date(s)
McClellan, Roger Director His experiences at Hanford, development of the Lovelace program, general.	Inhalation Toxicology Research Institute, Lovelace Foundation, Albuquerque	September 26, 1981, and correspondence
McGrew, Thomas Environmental programs.	U.S. Department of Energy	April 4, 1980
Meinhold, Charles Head, Safety and Environmental Protection Division Broad aspects of program, special consideration of Marshallese dosimetry. Joint interview with Edward Lessard part of the time.	Brookhaven National Laboratory	September 17, 1982
Miller, Leon Professor of Radiation Biology and Biophysics and of Biochemistry (retired) History of tracer chemistry.	University of Rochester Medical Center	May 30, 1978
Morgan, Karl, Professor (retired) Formerly Head, Health Physics Division General, his career, radiation protection standards, research.	Georgia Institute of Technology Oak Ridge National Laboratory	April 20, 22, 1979
Morrow, Paul Professor Radiation Biology and Biophysics and of Pharmacology and Toxicology Analytical problems, work at Tennessee Eastman Corporation, industrial hygiene, inhalation toxicology and physiology.	University of Rochester Medical Center	June 1, 1978; and several subsequent discussions
Myers, William Professor of Radiology History of nuclear medicine.	Ohio State University	June 5, 1981
Neuman, William Professor of Radiation Biology and Biophysics (deceased) Uranium and bone, general plans, World War II work.	University of Rochester Medical Center	May 26, 1978
Noonan, Thomas Professor (retired) History of laboratory, early work with radioisotopes at the Univ. of Rochester.	Comparative Animal Research Laboratory, Oak Ridge (formerly UT-AEC Farm) University of Rochester Medical Center	April 18, 1979
Norris, William (retired) Bone seekers.	Argonne National Laboratory	September 7, 1978
Norwood, W. D. "Dag" Medical Officer (retired) Clinical management of radionuclide exposure cases, medical care of radiation workers.	Hanford Works (General Electric Company) Battelle, Pacific Northwest Laboratories	June 4, 1979

Name and Position	Institution	Date(s)
Osterburg, Charles Environmental programs.	U.S. Department of Energy	April 7, 1980
Palmer, Ray Whole-body counting. Joint interview with F. Cross.	Battelle, Pacific Northwest Laboratories	June 4, 1979
Palmiter, Claire (retired) Work of the Federal Radiation Council. First interview in San Diego.	U.S. Environmental Protection Agency Formerly Federal Radiation Council	November 11, 1978, April 2, 1985
Park, James Biology & Chemistry Dept. Experimental work with plutonium at Battelle.	Battelle, Pacific Northwest Laboratories	June 6, 1979
Parker, Herbert Former Manager and Staff Scientist (deceased) History of entire field with emphasis on early years.	Hanford Works (General Electric Company) Battelle, Pacific Northwest Laboratories	June 4, 1979
Ragan, Harvey Iodine experiment, fallout, pathology.	Battelle, Pacific Northwest Laboratories	June 8, 1979
Reynolds, Orr Executive Secretary General, and role of Office of Naval Research, radium chapter.	American Physiological Society	March 28, 1980
Richmond, Chester Associate Director His work at Los Alamos plus general overview.	Oak Ridge National Laboratory	April 18, 1979
Robertson, James Nuclear medicine, dosimetry. Interview at Toronto, Ontario, Canada.	Mayo Clinic Now DOE	May 15, 1978
Rohwer, Paul Health and Safety Research Division (now Head of Health Physics) Plowshare, Oak Ridge Environmental Program, assessment of former sites.	Oak Ridge National Laboratory	April 13, 1979, and subsequent corres- pondence and conferences
Romney, "Van" Professor The UCLA plant experiments and work at NTS.	University of California, Los Angeles	October 13, 1978, and subsequent visits
Ross, Donald Inhalation toxicology, industrial hygiene in AEC.	DOE Headquarters, Germantown	March 16, 1979, March 31, 1980
Ross, Joseph (deceased) UCLA programs, NTS involvement, control of data.	University of California, Los Angeles	October 13, 1978

Name and Position	Institution	Date(s)
Ross, Martha Oral history.	Bethesda, MD	April 7, 1980
Rothstein, A. Rochester uranium work.	Hospital for Sick Children Toronto, Ontario	May 17, 1978
Rundo, John Earlier work at Harwell, thorium, polonium, plutonium, radium, instrumentation. Interview at Lake Geneva, Wisconsin.	Argonne National Laboratory	October 15, 1981
Russell, William Biology Division Genetic studies with internal emitters. Joint interview with Dr. Cumming.	Oak Ridge National Laboratory	April 20, 1979
Sanders, Charles Biology & Chemistry Dept. His work with actinides.	Battelle, Pacific Northwest Laboratories	June 7, 1979
Schulte, Harry Research at Los Alamos; bioassay, industrial hygiene. Interview in San Diego.	Los Alamos Scientific Laboratory	March 22, 1980
Seaborg, Glenn Professor Former Chairman Chapters 6 and 7, history of actinides.	University of California, Berkeley U.S. Atomic Energy Commission	October 22, 1980
Seymour, Allyn Professor Aquatic biology programs, radioecology, Pacific and Alaskan tests, chapters 11-13.	University of Washington School of Fisheries	June 1, 1979, October 7, 1983, and letters
Shilling, Charles Executive Director Formerly Deputy Director, Division of Biology and Medicine Office of Naval Research, radium chapter, general operation of AEC programs.	Underwater Medical Assoc. AEC	June 7, 1978, March 28, 1980
Shoup, Sam (retired) Role of Oak Ridge Operations Office in internal emitter research. Puerto Rico.	Oak Ridge Operations Office AEC	April 10, 1979
Sikov, Melvin Embryo and fetus.	Battelle, Pacific Northwest Laboratories	June 6, 1979
Smith, Frank Associate Professor of Radiation Biology and Biophysics Uranium and fluoride work.	University of Rochester Medical Center	June 1, 1978
Smith, Victor Therapy for deposited radionuclides.	Battelle, Pacific Northwest Laboratories	June 7, 1979
Soldat, Joseph Internal emitter dosimetry, environmental transfer.	Battelle, Pacific Northwest Laboratories	June 7, 1979

Name and Position	Institution	Date(s)
Spiers, William Radiological physics, bone seekers, dosimetry. Interview in 1979 at Richland, Washington; in 1981 at Lake Geneva, Wisconsin.	United Kingdom	June 9, 1979, October 9, 1981
Sterner, James, Professor Medical Director Uranium and health problems of industrial hygiene in MED.	University of California, Irvine Eastman Kodak Company and Tennessee Eastman Corporation	April 7, 1978
Stover, Betsy, Professor Chapter 8, general philosophy.	University of North Carolina Formerly at University of Utah	December 7, 1980
Sullivan, Maurice Gastrointestinal transfer and toxicity on ingestion.	Battelle, Pacific Northwest Laboratories	June 6, 1979
Taplin, George (deceased) Nuclear medicine, UCLA work at NTS.	University of California, Los Angeles	February 7, 1979
Terrill, James USPHS (retired) Radium literature, role of PHS in internal emitter research.	Food and Drug Administration	April 4, 1980
Thomas, John Radiological physics, tracers.	University of Pennsylvania	July 12, 1979
Thomas, Robert Very broad.	Los Alamos National Laboratory, now Headquarters, DOE	September 22, 1981, and subsequent letters and visits

Appendix B People and Places

A. General

This book goes to considerable lengths to describe the origin and development of specific projects and to name the people most concerned with them. This was especially true for what I have called the "king-sized experiments" and other major experiments, during and after World War II, at Argonne, Lovelace, Hanford, the Metallurgical Laboratory, Rochester, and Utah, among others. Nevertheless, a recapitulation of the American laboratories and the people whose work was quoted frequently may be useful; it is attempted in this Appendix.^(a)

Something of the milieu in which it all operated is also apparent in the text and in the preface. However, this book is by no means a history of the atomic energy effort in a broad sense. Hence, this Appendix is, except for citing a few useful general works, specific to the people and places discussed in the book.

B. Pre-World War II

The sites most involved with the biomedical problems of radioactivity in the earlier years are apparent in the four chapters on natural radioactivity (chapters 1 through 4) and in chapter 5 that deals, in part, with accelerators and accelerator-produced radionuclides. It was an international effort.

As is clear from chapter 3, the earliest research and clinical investigations occurred over more than a century before the discovery of radioactivity and were in connection with the health problems of miners. This was concentrated in Europe, particularly Germany and Czechoslovakia, as described in some detail in that chapter. There was much less activity on the uranium miner problems in the United States, although other facets, such as pneumoconiosis, effects of silica and of toxic gases, received considerable attention during the pre-World War II years in other types of mines.

(a) Remember our scope did not allow for in-depth discussions of the organization and operation of laboratories abroad, even though their work is quoted frequently.

The problems of the luminous dial painters, radium chemists, and radium patients were, by contrast, very actively under study in the United States. This centered at Massachusetts Institute of Technology (MIT) under R. D. Evans and colleagues as described in detail in chapter 1. There were significant but lesser contributions from the U.S. Public Health Service (PHS) among others.^(a)

During the decade of the 1930s, almost every major accelerator (cyclotron) had at least some involvement with biology and medicine. Most actively engaged were those at Berkeley (John Lawrence, Joseph Hamilton, and colleagues); MIT-Massachusetts General Hospital (MGH) (Robley Evans, Joseph Aub, Arthur Roberts, and colleagues); Rochester (William Bale, Wallace Fenn, Lee Du Bridge, S. Barnes, Paul Hahn, George Whipple, and colleagues); and Washington University, St. Louis (Arthur Compton, A. H. Allison, and colleagues, and later, Martin Kamen). The laboratories at Berkeley and MIT-MGH were the furthest into research leading to the discoveries of the 1940s in biomedical science, but all were into tracer chemistry and radiochemistry. Much that led later into the field of nuclear medicine was begun in those prewar facilities and by those pioneers. As described in chapter 5, the collaboration of biologists, physicians, and physicists was essential and became highly developed in those days.

C. Period of World War II (The Manhattan District-MED)

The giant of this period, for our purposes, was the Metallurgical Laboratory based in Chicago. Since most of the Berkeley work was reported in Metallurgical Laboratory reports, the giant can be said to have had his feet firmly planted in both Illinois and California. The biomedical program was presided over by Robert S. Stone, a radiologist from San Francisco, with major direction from MED Headquarters Medical Division, viz., Stafford L. Warren and his deputy Hymer Friedell.

The Chicago biomedical group was headed in part by K. C. Cole with Raymond Zirkle in biophysics; with the radioisotope toxicology aspects in the hands of R. Abrams, D. S. Anthony, E. S. G. Barron, R. D. Finkle, L. O. Jacobson, Walter Kisielecki, H. Lisco, J. J. Nickson, William Norris, C. L. Prosser, E. R. Russell, T. P. Singer, and Albert Tannenbaum; and with systematic histopathology presided over by William Bloom. In the later years, Miriam P. Finkel and Jack Schubert joined and continued well into the postwar years.

A portion of the Chicago Met Lab work utilized external radiation sources, but a surprisingly large part of their biomedical effort involved radionuclides. This was undoubtedly in part because the major physicochemical activities with plutonium and the other transuranium elements, under Glenn Seaborg and his associates, were going on close by.^(b)

The group at Berkeley, which reported as part of the Metallurgical Laboratory, was, of course, dominated by Joseph Hamilton, but there was a capable

(a) The role of the PHS in studies of radium and those individuals who had received radium extends well beyond that described in chapter 1. A book on the history of the PHS's involvement with radiation matters by James Terrill, still in preparation (personal interview 1980), should spell this out more completely.

(b) These were not in the same building, and they were separated by the stringent security restrictions of the day as well as by a few city blocks. Nevertheless, the chemistry group and biologists knew what was important.

cadre of colleagues such as Kenneth Scott, Dorothy Axelrod, Harold Copp, J. Crowley, and Lester Van Middlesworth. These were joined in the later years by Patricia Wallace, who later became Patricia Wallace Durbin and who is still carrying forward internal emitter research at Berkeley. Unfortunately, nearly all of the others scattered into other fields at the end of World War II, and Joe Hamilton died of leukemia at too young an age.

As at Chicago, there was other radiation work. This was in the sphere of Ernest and John Lawrence and in the Donner Laboratory, and the Virus Laboratory with which we associate names such as Cornelius Tobias, Hardin Jones, Melvin Calvin, Lowry Dobson, and others.

A second major center for biomedical research under the MED, separate from the Met Lab, was the University of Rochester Atomic Energy Project at the University of Rochester School of Medicine and Dentistry in Rochester, New York.^(a) Of the three divisions of the project, Biophysics, Medical, and Pharmacology, headed respectively by W. F. Bale, J. W. Howland, and H. C. Hodge, major internal emitter research occurred in two. The enormous enterprise with natural uranium, described in chapters 2 and 9, was in the Pharmacology Division. The work with polonium, plutonium, and radium was centered in the Biophysics Division. Both of these resulted in major postwar monographs. In the Pharmacology Division, much depended on the scientific acumen and dedication of people like A. L. Dounce, W. F. Neuman, A. Rothstein, H. Stokinger, and others, while in the Biophysics Division principal figures besides W. F. Bale were G. Boyd, G. Casarett, R. Fink, R. Metcalf, H. Silberstein, G. Suter, and colleagues, with tissue pathology presided over later by G. W. Casarett. The Rochester Atomic Energy Project was directed, during most of the war years, by Andrew Dowdy from the Department of Radiology.

There was also a large effort at Rochester with external radiation sources. Particular mention should be made of a large mouse genetics program under the direction of Donald R. Charles. This program, while it had problems with infections, etc., can be regarded as a forerunner of the "megamouse" experiment done in the postwar years at Oak Ridge.

As described in chapters 2, 8, and 9, Rochester used the inhalation route for many of its exposures to uranium and, to a lesser extent, other radionuclides. It became, and has continued to be, a center for inhalation toxicology.

The Los Alamos Scientific Laboratory was not into biomedical research during the war years, as is described in the text. They were heavily involved in bioassay and health protection. Key figures were Dr. Louis Hempelmann and later Wright Langham.

The key studies in aquatic biology at the University of Washington and at Hanford constituted a third center. These have been described in so much detail in the environment chapters (11 through 15) that little more needs to be added here. We will always remember the names Kelshaw Bonham, Lauren Donaldson, Allyn Seymour, Arthur Welander, and others at Seattle, and Richard Foster and his colleagues at Hanford.

Before we conclude this brief recapitulation of people and places of specific import to the subject matter of this book during the war years, a few of the

(a) The Medical Director of the MED, Stafford L. Warren, was Professor of Radiology at Rochester and knew the staff and the potential well enough to place the second major biomedical activity there.

general discussions of the wartime effort should be noted, since these might give the reader a broader overview of the milieu in which the research was done. Those cited are a few of many. They are listed in chronological order of publication; all are postwar, but are primarily about the war years.

D. The Post-World-War-II Years

The principal sites and people of this era of biomedical research with radio-nuclides have been taken up in depth (chapters 1, 2, 3, 4, 8, 9, 10, 11-15, 19, 20) sufficient to make only general comments necessary here.

Brookhaven

Brookhaven National Laboratory (BNL) was entirely a postwar creation. Biomedical work has thrived in the very strong medical division; in the earlier years in a strong botany program that was both basic and applied; and in terms of environmental contamination, including recently the dosimetry for the exposed Marshall Islanders in what was the Health Physics Division and is now the Safety and Environmental Protection Division.

The Medical Division was originally headed by Lee Farr whose interests in neutron capture therapy with uranium we saw in chapter 2. For many years it was headed by Victor Bond, a broad-gauge radiation biologist and physician. Associated with the Division have been the physicians Eugene Cronkite and

Robert Conard, who have had more to do with the care and investigation of the Marshall Islanders than any other individuals.^(a) Stanton Cohn has operated an important program in mineral metabolism using the whole-body counter. Other BNL people can be seen in the interview listing of Appendix A (e.g., Carsten, Cowan, Hull, Lessard, Meinhold).

At the cellular level, Drs. Bond, Carsten, Cronkite, and others, produced detailed investigations of microdosimetry with tritium and other low energy beta emitters. Particular emphasis was placed on the troubling problem of possible transmutation effects.

The laboratory and field experiments with plants concerned largely external radiation sources. They are not described in any detail in this book, but we should note that Arnold Sparrow and his wife Rhoda developed a bona fide center for radiation botany.

Brookhaven has a medical reactor and access to many other sources of external radiation and has recently added a program in inhalation toxicology.

Chicago

The former Met Lab facility moved from the University of Chicago campus to the Le Mont site of the Argonne National Laboratory. The director of the Biology Division for the majority of the postwar years of significance to this book was Austin M. Brues, who had had early experience with radium (see chapter 1). Miriam Finkel continued long-term studies with many colleagues, and her husband, Asher Finkel, joined the Argonne Radium Studies along with Robert Hasterlik, Charles Miller, and others. William P. Norris continued his work on bone seekers, partly in collaboration with Walter Kisielewski; M. White Rosenthal and Arthur Lindenbaum engaged in definitive studies of the role of chemical state on the metabolism of radionuclides; Jack Schubert did his pioneer work with radiocolloids and the therapeutic removal of radionuclides; John Marshall developed his model for alkaline earth metabolism in bone; Henry Lucas and Andrew Stehney followed out radium and radon problems; Douglas Grahn looked into genetic effects of deposited radionuclides; among other things; and in later years, John Rundo, A. T. Keane, R. E. Toohey, M. H. Bhattacharyya, and R. P. Larsen^(b) joined the roster.

In addition to the Biology Division, there was a Radiological Physics Division, headed by Leo Marinelli, which made many contributions to the internal emitter field.

In the late 1960s, the Center for Human Radiobiology was developed at Argonne, as described in chapter 1. This was directed by Robert Rowland and included many former members of the Biology Division (e.g., Schlenker, Brues, Marshall, Stehney, Lucas, P. Failla, Holtzman, Keane).

As noted in chapter 1, the Argonne Cancer Research Hospital (ACRH) was built by the Atomic Energy Commission (AEC) near the University of Chicago Medical School. It assimilated several key investigators from the MED days and provided very important clinical facilities and expertise for the Argonne Radium Studies, as well as for other phases of work on radiation effects. Names to

(a) They also did work in many other fields. Cronkite, for example, is well-known as a hematologist.

(b) Remember these are limited to those working with radionuclides more or less full time.

remember especially are Leon O. Jacobson, Lawrence H. Lanzl,^(a) and colleagues. In still later years (1970s), the ACRH became the Franklin McLean Memorial Institute of the University of Chicago, but it has since lost some of its identity.

Hanford—Pacific Northwest Laboratory

The postwar development of Hanford is traced in chapters 8, 9, 11 through 15, and 19. The blossoming of a first-class biology program from what had been largely a monitoring and control operation is due to the foresight and persistence of Herbert M. Parker, the wartime manager of the health aspects of the plutonium production operation, who became postwar manager of the entire Hanford facility. The first manager of the Biology Division was Harry Kornberg. He did important research on tritium, on plants, and in other areas, some of it in collaboration with R. C. Thompson, who has remained a pillar of the radio-nuclide community ever since. Leo Bustad operated a series of important long-term experiments until his departure to the University of California at Davis. W. J. Bair became manager of what was called the Pharmacology Operation and developed an outstanding program in inhalation toxicology with the many colleagues named in chapter 9. This operation is still under way, although Dr. Bair has become manager of a large portion of the entire biomedical effort of the successor to the Hanford laboratory, Pacific Northwest Laboratory (operated by Battelle Memorial Institute). The laboratory research was augmented by many others, such as Fred Cross, Pat Hackett, B. J. McClanahan, Jim Park, Harvey Ragan, Chuck Sanders, Mel Sikov, Victor Smith, Bruce Wachholz, and others named in Appendix A.

Meanwhile, the medical aspects were guarded by W. D. "Dag" Norwood in a manner that led to the eventual development of the Hanford Environmental Health Foundation, which now manages the U.S. Transuranium and Uranium Registries.

The environmental work continued under Richard Foster with a series of notable colleagues such as Wayne Hanson. In more recent years, it was managed by Burton E. Vaughan, in close association with Ray Wildung, et al.

Like many other laboratories of the AEC era, the Battelle group has now diversified into many nonnuclear areas but is applying the same basic research techniques with emphasis on mechanisms.

Health and Safety Laboratory (HASL)^(b)

This group was an operational arm of the AEC. It developed around the problems of industrial hygiene and bioassay for uranium, supplied major aid to the PHS regarding the uranium miner and miller problems in the western states, was a center for measurements (in the thousands) and ideas during the entire fallout controversy, and has continued under the Energy Research and Development Administration (ERDA) and the Department of Energy (DOE) as the Environmental Measurements Laboratory. Most of the experiments around problems of the postwar years have been improved and advanced by contributions of equipment, know-how, and/or ideas from HASL. Their contributions to the fallout work were enormous and done "in house."

(a) Dr. Lanzl very kindly supplied a picture of the ACRH and a full history that unfortunately we could not include in detail here.

(b) Now Environmental Measurements Laboratory.

In its earlier days, the Laboratory was directed by Merrill Eisenbud who later went to New York University. John Harley then became director. Key figures in the group for internal emitter work were Roy Albert, A. J. Breslin, E. P. Hardy, Jr., J. H. Harley, N. Harley, P. W. Krey, James McLaughlin, J. Rivera, H. Spencer, H. L. Volchok, and G. A. Welford, among others.

Lawrence Livermore Laboratory

Like Brookhaven, the Lawrence Livermore National Laboratory was entirely a postwar creation. As noted in the environment chapters (11 through 15), the biomedical program was developed to attack problems of environmental contamination, especially fallout and aspects of Project Plowshare. The principal names to be noted are: Lynn Anspaugh, Y. C. Ng, V. E. Noshkin, W. L. Robison, and colleagues. The laboratory is now proceeding on a very broad front. Edward Teller was the original director.

Los Alamos

As described in chapters 7, 8, 16, 19, and elsewhere, Los Alamos Scientific Laboratory (later Los Alamos National Laboratory) did not have a formal biomedical program during the war. It did have much interest in bioassay problems. The postwar activities developed rapidly and were led primarily by Thomas Shipman, with carry-over help from Louis Hempelmann,^(a) and after him, George Voelz, on the medical side, and on the laboratory side by Wright Langham, plus a strong corps of colleagues such as R. E. Carter, P. N. Dean, H. Foreman, J. E. Furchner, J. Healy, Harry Jordan, J. E. London, J. McInroy, W. Moss, E. A. Pinson, Chester Richmond, John Storer, Agnes Stroud, and more recently, R. G. Thomas. Wright Langham was a towering figure in the field of radionuclide metabolism and effects, both pre- and postwar. He grew up with plutonium, and much of his interest was centered on it and other actinides—enough so that he would early be called “Mr. Plutonium” of the biomedical world. However, he also had keen interests in fallout, standard setting, etc. Indeed, there were few areas of the internal emitter field into which he did not have significant input. In later years, the Los Alamos group broadened considerably into molecular radiobiology. There was also a strong industrial hygiene operation under the direction of Harry Schulte.

Lovelace

The development of the Inhalation Toxicology Research Institute (ITRI) at the Lovelace Foundation in Albuquerque and its principal people are described in depth in chapters 8 and 9. After initial direction by R. Lovelace and C. S. White, with capable assistance from R. G. Thomas, T. Mercer, J. K. Scott, and others, the management went to Roger McClellan, formerly of Hanford and AEC Headquarters. With a strong team made up of individuals like Bruce Boecker, A. Brooks, Fletcher Hahn, C. H. Hobbs, R. Jones, George Kanappily, J. A. Mewhinney, Bruce Muggenburg, H. C. Yeh, and others, ITRI has become, along with Battelle, one of the strongest centers in the world for inhalation toxicology. Almost all of its earlier work concerned radionuclides. They are now into a large variety of energy-related inhalation and conventional toxicological investigations.

(a) Hempelmann was by then at the University of Rochester. However, he played a key role in medical care of the Los Alamos workers during the war and continued actively in the follow-up studies on the plutonium workers.

Massachusetts Institute of Technology

During the post World War II period, the so-called Radioactivity Center at MIT continued to be the center for studies on radium in humans, except for the group at Argonne National Laboratory doing the Argonne Radium Studies (chapter 1), and (to a lesser extent) radon and the uranium miner problems. The project leader was still Robley D. Evans, who continued to surround himself with competent colleagues and students, such as C. J. Maletskos, R. A. Dudley, R. Schlenker, M. M. Shanahan, N. C. Telles, and others. There were regular and detailed annual reports that included full medical data on the persons whose body burdens of radium and related isotopes had been determined during that year. There were also regular open literature publications from this consistently active group, which merged in 1970 into the Center for Human Radiobiology at Argonne National Laboratory. As always, collaboration between physical and biological scientists was emphasized.

Oak Ridge

The high quality biology program at Oak Ridge National Laboratory (ORNL) developed by Alexander Hollaender eschewed internal emitter research, except for some relatively recent forays by William Russell and his colleagues into genetic effects of deposited radionuclides. This is being done partly in collaboration with Argonne National Laboratory (Douglas Grahn).

The Health Physics Division at Oak Ridge did not carry out large amounts of conventional laboratory research with animals, although B. Fish and colleagues did some work with uranium. On the other hand, the Division became the world center for internal emitter dosimetry. Walter Snyder (now deceased) was the towering figure in this effort, with the Division Head, Karl Z. Morgan, supplying encouragement and advice. The capable and patient hands of Mary Rose Ford and Mary Jane Cook made an enormous difference in the output of this group. Also, Isabel Tipton carried out important work on trace elements in human tissues in her laboratory at the University of Tennessee, under Oak Ridge support. In later years, John Auxier added to the internal emitter activities, while John Poston and Keith Eckerman became associated with the internal dosimetry effort and its relationships to Medical Internal Radiation Dose (MIRD). Chester Richmond moved over from Los Alamos to assume a high administrative post at ORNL, but kept his interest in radionuclide research.

The University of Tennessee-Atomic Energy Commission Farm, later CARL, is described in detail in chapter 13 (Cycil Comar, F. W. Lengemann, R. Wasserman, T. Noonan, et al.).

University of California, Berkeley—Lawrence Radiation Laboratory

With the dismantling of the "medical cyclotron" and razing of the Crocker Laboratory (see chapter 6), the internal emitter activities went to a site above the campus, part of the Lawrence Radiation Laboratory, and are represented in the postwar years primarily by Patricia Durbin and colleagues. The work is cited in extenso in chapters 8, 16, 19, and elsewhere.

University of California, Davis

The story of the development of this program is given in detail in chapter 8 and its findings in chapter 13. In the early postwar years, a beagle colony was

developed under the leadership of A. C. "Bud" Anderson. It concerned effects of external radiation.

When the need to develop a "king-sized experiment" around the problems of ingested strontium as part of the fallout activities arose, the Davis campus became the site. Shortly it came under the direction of Leo K. Bustad, who came to Davis from Hanford and remained for many years. When Bustad went to his alma mater, Washington State University, as dean of the School of Veterinary Medicine, Marv Goldman, his colleague and University of Rochester graduate, succeeded him as director. It was known as the Radiobiology Laboratory until diversification prompted a name change to "Laboratory of Energy Related Health Research." Names to remember besides Bustad and Goldman, are R. J. Della Rosa, S. Book, L. S. Rosenblatt, M. H. Momeni, R. R. Pool, N. J. Parks, and O. Raabe, after his transfer from Lovelace.

University of California, Los Angeles (UCLA)

The UCLA project grew de novo directly after the war as sort of a clone to the Rochester project. When Stafford Warren left the MED post to become dean of the new Medical School at UCLA, he wanted to keep his finger in the atomic energy field. He was enabled to do so by having the AEC support a project on the campus somewhat akin to the Rochester Project that he squired in MED days. It participated especially actively in the weapons testing program. Some of the people concerned were A. W. Bellamy, M. Greenfield, Kermit Larson, H. M. Mook, J. W. Neel, H. Nishita, J. H. Olafson, "Van" Romney, and A. Wallace. Some of these have spent most of their careers on the ecological and other aspects of fallout with correlated laboratory experiments. Others (Taplin, Bennett, Riley) worked into various aspects of nuclear medicine and drifted away in part from the project to the Radiology Department. The work of the former group is seen most in the environment chapters (11 through 15) and of the latter group, in the ones on nuclear medicine (20) and inhalation toxicology (9, 10).

University of Rochester

After World War II, the University of Rochester Atomic Energy Project became an academic department of the medical school, viz., Radiation Biology, then Radiation Biology and Biophysics. Many of the key figures from the wartime research remained, and the programs continued, but with more fundamental overtones. Those remaining included G. Casarett, K. Lauterbach, Paul Morrow, William Neuman, Aser Rothstein, as well as the division heads named earlier (Bale, Hodge, Howland). John B. Hursh returned to Rochester from the Radiation Laboratory at MIT. J. N. Stannard returned from war duties at the National Institute of Health and in the U.S. Navy. The extension of the uranium work under H. C. Hodge, with help from L. Leach and others, is described in chapter 2. The continuation of the work with alpha emitters, radium, radon, and polonium, by Hursh; polonium and inhalation toxicology by Stannard and colleagues L. Casarett, Mercer, Morken, Morrow, Smith, Thomas, Wilson, are described in chapters 1, 4, 9, and 14.

The basic contributions of Neuman and Rothstein are highlighted in chapter 21, along with other such contributions from the Rochester group. G. W. Casarett, whose name we saw in the MED work from Rochester, for many years continued the polonium research he was associated with for his doctoral thesis,

but later became involved with general radiation pathology, radiology, and large animal experiments with external radiation.

The postwar Rochester project did much more than the internal emitter research and inhalation toxicology described in this book. It was a center for graduate education in the new field of atomic energy as applied to biology and medicine. It was this author's privilege to spearhead this effort. Rochester also carried out much basic research in cellular radiobiology and general biophysics.

Many of the AEC laboratories were requested to participate in the weapons testing program. Except for UCLA, Rochester seems to have contributed as much or more in manpower and equipment as any of the major projects, well beyond the National Laboratories (see especially Wilson and Thomas).

Finally, Dr. Hodge's pharmacology division became the first line of defense for AEC in general toxicology. Whenever a new substance or process with potential toxicologic aspects came to light, the AEC would ask Rochester to get an initial reading on the substance or process, whether chemical or radioactive. It was traditional for the request to arrive on Friday, with a preliminary answer expected by the next week!

As a project at first associated physically and administratively with a major medical school, the Rochester group was probably one of the most academically oriented ones. Yet, it took part in many very practical enterprises.

The director for many years was Dr. Henry A. Blair, a physicist turned biophysicist and radiation biologist who made significant contributions to the analysis of life-span shortening by radionuclides and by external radiation.

University of Utah

The first of the "king-sized experiments" with radionuclides was developed in the Department of Anatomy at the University of Utah Medical School in Salt Lake City. It is described in detail in chapter 9, including the "founding fathers" and the influence of John Z. Bowles, dean of the school. It has been and remains a key laboratory in internal emitter research. Names to remember are J. Arnold, D. R. Atherton, F. W. Bruenger, T. and J. Dougherty, W. S. S. Jee, R. D. Lloyd, C. W. Mays, J. E. Rehfeld, W. Stevens, B. J. Stover, G. N. Taylor; and, in recent years, M. E. Wrenn.

Others

There were many other laboratories that developed *de novo* after the war that had significant involvement with "internal emitters." Examples are the Armed Forces Radiobiology Laboratory in Bethesda;^(a) the Naval Radiological Defense Laboratory in San Francisco; the University of Tennessee-AEC Experimental Farm in Oak Ridge; the Laboratory of Physical Biology at Cornell University; the Mound Laboratory at Miamisburg, Ohio, which had a program with polonium for a few years; the Public Health Service Laboratories in Nevada, Alabama, Massachusetts, and Maryland, etc. Each of these is described in sufficient detail in the text to make further exposition here redundant. The Armed Forces Institute program embraced mostly external radiation problems.

(a) This organization was set up at about the time of the demise of the Naval Radiological Defense Laboratory. It had a much more limited program with primary emphasis for many years on effects of high doses of external radiation on behavior and performance. There was not much work in the radionuclide field. In later years, the laboratory developed the diversified programs in molecular radiobiology and related areas.

Finally, the "king-sized" experiments at Hanford, Utah, University of California at Davis, and at Lovelace (ITRI) were described in full detail in chapters 8, 9, and 13. The reader is referred to those expositions for the full story.

General Literature

The early postwar years easily became the subject of personal narratives or periodic reviews, something like those described in part C of this Appendix. Among these are books on the development and history of the AEC, a unique administrative structure within our government, the Atoms for Peace Program, and miscellaneous biographies. A few are listed below.

Hewlett, R. G. and O. E. Anderson, Jr. 1962. *The new world. 1939/1946*. Volume I of a history of the United States Atomic Energy Commission. University Park, Pa.: Penn State Univ. Press.

Hewlett, R. G. and F. Duncan. 1969. *Atomic shield. 1947/1952*. Volume II of a history of the United States Atomic Energy Commission. University Park, Pa.: Penn State Univ. Press.

Allardice, C. and E. R. Trapnell. 1974. *The Atomic Energy Commission*. The Praeger Library of U.S. Government Departments and Agencies. New York-Washington: Praeger Publishers.

Note

All names of authors and individuals otherwise referred to in the text have been placed in Index I. This is called "People," since not all individuals were cited by virtue of being an author. It is hoped that this rather extensive listing will be used to extend and amplify the rather cryptic references possible in this Appendix. A separate index (Index II) was prepared to permit searching for specific institutions or organizations. This should be used to flesh out the details of institutions and organizations cited in this Appendix and to add to the cadre that was, perforce, truncated here.

Appendix C

The National Nuclear Energy Series (NNEs) Hiatus

Throughout the review of the Manhattan Engineering District (MED) work of the World-War-II period, we had numerous occasions to refer to and to review, in part, a series of Metallurgical Laboratory reports referred to cryptically as the "NNEs Hiatus." This set of fifty documents (originally labeled "PPR" for Plutonium Project Reports), many of them in several sections of considerable length, was intended for publication as volumes 22F, 22G, and 22H of Division IV of the NNEs, the monumental postwar monograph series on the work of the MED. Volumes 22F-H were never published because of the upheavals in personnel and planning during the early postwar years when the NNEs volumes were being assembled, and because of the need for the designated editor for the Chicago volumes, Raymond E. Zirkle, to concentrate on other volumes for which he had manuscripts in hand. Why these particular manuscripts were never received by McGraw-Hill or the NNEs editorial board is not clear.^(a) Most of the papers had appeared in the report literature, classified in the beginning, and were gradually declassified. A few were published eventually in the open literature, but the organized progression envisioned for the volumes was lost. For this reason, the titles and MDDC report number, if available, and a few other details are given in this Appendix for the fifty papers planned, along with a quick summary of the NNEs.

Many of the reports were available in this author's files from years of careful accumulation or were obtained from DOE archives, the capacious files of Dr. Patricia Durbin at Berkeley, and other friends with saving habits such as Hymer Friedell at Case-Western Reserve University. Some of the most important and/or comprehensive reports that had very little postwar distribution are reviewed in some depth in the pertinent chapters of this book. Indeed, this feature was one of the original reasons behind writing the book.

(a) Many of the reports were not very polished, many had significant gaps that the authors undoubtedly hoped to fill. In other cases, the authors had already turned to other things, returned to their home institutions, or otherwise found it nearly impossible to reach back to finish the revisions needed for publication.

Also, courtesy of Dr. Durbin, this author was able to see and use abstracts from Nuclear Science Abstracts of many of the reports for which he could not obtain full copies. Referral to these abstracts and the "CH" number corresponding to the MDDC number are being kept on file by the author and will be supplied to interested readers on request, to the extent possible. Abstracts are not included here since this would overlap, unduly, the discussions in the text.

I am especially grateful to Dr. Durbin for her help in tracking down this material. My task was eased because she had already gathered many items, including a letter from William Vaden, Deputy Extension Manager of the AEC Division of Technical Information Extension, Oak Ridge, to Dr. R. K. Wakerling, Technical Information Division at Lawrence Radiation Laboratory, dated November 30, 1967, that enclosed the master listing.

List of Reports in the "NNES Hiatus"
(Volumes 22F, G, and H of the National Nuclear Energy Series)

Intended General Title: Metabolism and Biological Effects of Internal Emitters

Intended Running Title: Part V. Radiobiology Collected Papers

Paper No.	Title(a) and Authors	Report No.
1.	Preparation of Fission Products for Use in the Experimental Biology Section By A. Broido	MDDC-1244
2.	Methods of Analysis of Fission Products in the Experimental Biology Section By P. C. Tompkins, A. Broido, and L. Wish	MDDC-616
3.	The Quantitative Estimation of the Activity of Beta particle Emitters By A. Broido, J. Teresi, and P. Tompkins	MDDC-598
4.	Methods for the Quantification of Radium By P. C. Tompkins, W. P. Norris, L. Wish, and R. D. Finkle	MDDC-699
5.	The Handling of Radioactive Materials in the Experimental Biology Section By P. C. Tompkins, A. Broido, and J. D. Teresi	MDDC-377
6.	An Improved Method for Cutting Undecalcified Bone Sections and its Application to Radio-autography(b) By D. J. Axelrod	MDDC-450
7.	Calculations of Dosage Due to Internal Emitters(b) By W. Cohn	No Number
8.	The Metabolism of Carrier-free Fission Products in the Rat By K. G. Scott, R. Overstreet, L. Jacobson, and J. G. Hamilton	MDDC-1275
9.	Radiotoxicity of Injected Sr ⁸⁹ for Rats, Mice, and Rabbits I. Introduction: Methods By D. Anthony, K. Lathrop, and R. Finkle	MDDC-1540
	II. Metabolism and Organ Distribution By D. Anthony, K. Lathrop, and R. Finkle	MDDC-1363

Paper No.	Title(a)	Report No.
	III. Lethal Action and Clinical Changes By D. S. Anthony, K. Lathrop, and R. H. Snyder	MDDC-1364
	IV. The Hematological Effects of Enterally and Parenterally Administered Strontium-89 in Mammals By E. L. Simmons and L. O. Jacobson	MDDC-1387
10.	Acute Radiotoxicity of (Ba-La) ¹⁴⁰ in Rats and Mice	
	I. Preparation and Administration of the Emitters By R. D. Finkle, R. H. Snyder, and P. C. Tompkins	MDDC-1248
	II. Metabolism of (Ba-La) ¹⁴⁰ By R. H. Snyder, W. E. Kisieleski, D. S. Anthony, and R. D. Finkle	MDDC-1279
	III. Effects on Weight and Food Intake of Animals Treated with (Ba-La) ¹⁴⁰ By R. H. Snyder, G. A. Sacher, and J. D. Teresi	MDDC-1343
	IV. Lethal Action and Clinical Symptoms By R. D. Finkle, R. H. Snyder, and W. E. Kisieleski	MDDC-1207
	V. The Effect of (Ba-La) ¹⁴⁰ on the Hematological Constituents of the Peripheral Blood of Rats and Mice By L. O. Jacobson	MDDC-1261
11.	Acute Radiotoxicity of Injected Cesium-144 in the Rat By D. S. Anthony and K. A. Lathrop	MDDC-1326
12.	Acute Radiotoxicity of Injected Yttrium-91 By D. S. Anthony	MDDC-1240
13.	Acute Radiotoxicity of Injected P ³² in Mice I. Metabolism and Survival By D. S. Anthony and R. H. Snyder	MDDC-881
14.	The Deposition of Plutonium and Certain Fission Products in Bone as a Decontamination Problem	AECD-2483
	I. Factors Affecting the Absorption of Radioactive Strontium from the Gut By D. H. Copp, D. M. Greenberg, and J. G. Hamilton	(c)
	II. Factors Affecting the Retention of Injected Radioactive Strontium By D. H. Copp, D. M. Greenberg, and J. G. Hamilton	(c)
	III. Effect of Age and Dietary Calcium on Radioactive Sr, Y, Ce, and Pu By D. H. Copp, M. J. Chace, and J. G. Hamilton	(c)
	IV. Effect of Treatment on Chronic Elimination of Radioactive Sr, Y, Ce, and Pu By D. H. Copp, L. Van Middlesworth, E. M. Cuthbertson, M. J. Chace, and J. G. Hamilton	(c)
	V. Uptake of Radioactive Sr, Y, and Pu in Healing Fracture Callus By L. Van Middlesworth, D. H. Copp, and J. G. Hamilton	(c)
	VI. Effects of Severe Phosphorus Deficiency By D. H. Copp, M. J. Chace, and J. G. Hamilton	(c)
	VII. Bone Radioautographs of Radioactive Sr, Y, Ce, Zr, and Pu By Dorothy Axelrod, D. H. Copp, and J. G. Hamilton	(c)

Paper No.	Title ^(a) and Authors	Report No.
15.	Production and Analysis of Radioactive Aerosols By E. Abrams, A. M. Potts, C. E. Beilman, I. Wender, W. Lohr, S. Postel, and L. L. Forker	MDDC-795
16.	Metabolism of Inhaled Fission Product Aerosols By R. Abrams, H. C. Seibert, A. M. Potts, W. Lohr, and S. Postel	MDDC-248
17.	Tracer Studies with Inhaled Eight-day Iodine By M. Dailey, I. Wender, and R. Abrams	MDDC-251
18.	Tracer Studies with Inhaled 1.0 Year Ruthenium By M. Dailey, I. Wender, and R. Abrams	MDDC-420
19.	Acute Toxicity of Inhaled 275-day Ce ¹⁴⁴ By H. C. Seibert and R. Abrams	MDDC-329
20.	Studies on the Inhalation of Fissionable Materials and Fission Products and Their Subsequent Fate in Rats and Man By K. G. Scott, D. Axelrod, J. Crowley, H. C. Lanz, and J. G. Hamilton	MDDC-1276
21.	Metabolism and Distribution of Inhaled Plutonium in Rats By R. Abrams, H. C. Seibert, A. M. Potts, L. L. Forker, D. M. Greenberg, S. Postel, and W. Lohr	MDDC-677
22.	Acute Toxicity of Intubated Plutonium Deposited in the Lungs By R. Abrams, H. C. Seibert, L. L. Forker, D. M. Greenberg, H. Lisco, L. O. Jacobson, and Eric L. Simmons	CH-3875
23.	Metabolism of Plutonium in Rats* By K. Scott, H. Fisher, Dorothy Axelrod, J. Crowley, A. J. Barber, and J. G. Hamilton	MDDC-1018
24.	A Comparison of the Metabolism of Plutonium (Pu ²³⁸) in Man and the Rat By J. Crowley, H. C. Lanz, K. G. Scott, and J. G. Hamilton	CH-3589
25.	The Toxicity and Metabolism of Plutonium in Laboratory Animals I. Introduction By R. H. Snyder and R. D. Finkle II. Methods By R. H. Snyder and W. E. Kisieleski III. The Metabolism of Injected Plutonium By R. H. Snyder, W. E. Kisieleski, B. Lawrence, and R. D. Finkle IV. The Survival and Growth of Plutonium-Injected Animals By R. H. Snyder, W. E. Kisieleski, and R. D. Finkle V. The Effect of Ingested Plutonium By R. H. Snyder, B. Lawrence, and R. D. Finkle VI. The Hematological Effects of Parenterally Administered Plutonium By L. O. Jacobson and E. L. Simmons	MDDC-1140

Paper No.	Title ^(a) and Authors	Report No.
26.	The Effect of Plutonium on Tissue Metabolism of Rats By E. S. G. Barron, R. Abrams, R. D. Finkle, and R. P. Rhoades	MDDC-1653
27.	Combination of Plutonium with Plasma Proteins (Electrophoretic and Chemical Analysis) By J. A. Muntz and E. S. G. Barron	MDDC-1268
28.	The Metabolism of Thorium, ^(b) Protoactinium, ^(b) and Neptunium ^(b) in the Rat By H. Lanz, K. G. Scott, J. Growley, and J. G. Hamilton	MDDC-648
29.	The Production of Radioactive Xenon for Animal Exposures By R. Abrams, C. E. Beilman, and L. D. Norris	MDDC-1325
30.	The Maintenance of Animals Containing Radioactive Materials By P. Britton, P. Lear, C. L. Prosser, and E. Tyree	MDDC-1243
31.	Apparatus for Injection of Animals with Dangerous Amounts of Hard Beta and Gamma Emitters By D. S. Anthony and W. O. Norris	AECD-2007
32.	An Apparatus for Maintaining a Slow and Constant Rate of Injection By R. H. Snyder, B. Lawrence, and R. D. Finkle	MDDC-270
33.	The Administration of Radioactive Materials to Animals by Tracheal Intubation By H. C. Seibert	MDDC-268
34.	Accumulation and Distribution of Radioactive Strontium, Barium-Lanthanum, Fission Mixture and Sodium in Goldfish By C. L. Prosser, W. Pervinsek, J. Arnold, G. Svihla, and P. C. Tompkins	MDDC-496
35.	The Lethal Action of X Radiation, Stable Isotopes of Fission Elements, Sr ⁹⁰ and (Ba-La) ¹⁴⁰ , upon Goldfish ^(b) By C. L. Prosser, C. W. Hagen, Jr., and W. Grundhauser	MDDC-1480
36.	Plant Studies ^(b) (The Fixation and Absorption of Fission Products by Plants) By L. Jacobson and R. Overstreet	MDDC-571
37.	Absorption and Fixation of Fission Products and Plutonium by Plants By L. Jacobson and R. Overstreet	CH-3588
38.	The Metabolism of Short-lived Air-borne Fission Products By H. C. Lanz and J. D. Teresi	MDDC-954
39.	The Effect of Clay on the Intestinal Absorption of Strontium By H. J. Curtis	MDDC-419
40.	The Transmission of Radio-strontium and Plutonium from Mother to Offspring in Laboratory Animals ^(b) By M. P. Finkel	MDDC-750

Paper No.	Title ^(a) and Authors	Report No.
41.	Studies of the Metabolism and Toxic Action of Injected Radium I. Metabolism, Lethal Action and Clinical Changes By W. P. Norris and H. B. Evans	AECD-1965
	II. Hematological Effects of Parenterally Administered Radium. A Comparison of Plutonium and Radium Effects By L. O. Jacobson and E. L. Simmons	AECD-2372
42.	The Excretion, Retention, Distribution, and Clinical Effects of Strontium-89 in the Dog I. Report of Experimental Work By M. N. Swift and C. L. Prosser	MDDC-1388
	II. Statistical Analysis of Excretion and Retention for Individual Dogs By G. Sacher	AECD-2108
43.	Comparative Action of Injected Sr ⁸⁹ on Splenectomized and Non-splenectomized Mice By L. O. Jacobson and E. L. Simmons	CH-3886
44.	Acute Radiotoxicity of Injected Na ²⁴ for Mice and Rats I. Metabolism and General Toxicity By R. D. Finkle and R. H. Snyder	AECD-2011
	II. The Effect of the Na ²⁴ on the Leucocytes of the Peripheral Blood of Mice By L. O. Jacobson, and E. L. Simmons	AECD-2036
45.	Effects of Insoluble Ingested Y ⁹¹ I. Introduction: Methods By D. S. Anthony	
	II. Metabolism By D. S. Anthony and W. Grundhauser	
	III. Acute Lethal Action By D. S. Anthony	
	IV. Measurement of Dosage By D. S. Anthony, W. Grundhauser, and G. Svihla	
	V. Chronic Lethal Action By A. M. Brues and W. Grundhauser	
	VI. Effects on Weight By D. S. Anthony and W. Grundhauser	
	VII. Pathological Effects By H. Lisco and G. Sacher	
	VIII. Hematological Effects By L. O. Jacobson and E. L. Simmons	AECD-2037
46.	Clinical Physiology of Dogs Injected with Plutonium By Elizabeth E. Painter, E. R. Russell, C. L. Prosser, Marguerite N. Swift, W. E. Kisieleski, and G. Sacher	CH-3858
47.	Effects of Sr ⁸⁹ and X Radiation on Goats By Marguerite N. Swift, C. L. Prosser, and E. S. Mika (Contributions by Leon O. Jacobson, Herman Lisco, George Sacher, Roberta Edwards, La Forne Little, Homer Hipple, and Oscar Klioze)	AECU-108

Paper No.	Title ^(a) and Authors	Report No.
48.	Radioautographic Methods By G. Svihla	
49.	The Effect of Folic Acid on the Response of the Peripheral Blood and Blood-forming Tissue of the Rat to Parenterally Administered Sr ⁸⁹ By L. O. Jacobson, S. P. Stearner, E. L. Simmons, and M. H. Black	ANL-4126
50.	Plutonium in Puncture Wounds and Lacerations. A Preliminary Study By R. D. Finkle, J. D. Teresi, R. H. Snyder, and J. J. Nickson	

(a) The titles use the nomenclature of the time and have not been changed; this includes the designation of isotopes.

(b) Published also in the open literature.

(c) Part of AECD-2483

The reader must be impressed by the extent to which the papers listed indicate both breadth and depth of coverage of what was at the time an essentially new field. Large areas of research encountered in the post-World-War-II studies described in this book can be seen foreshadowed or actually begun in the work of the MED. While quality and polish may be somewhat deficient in some papers, this performance and others like it belie the accusation sometimes heard that the MED biomedical studies were largely "hack work." We learned an enormous amount in a short time. It is remarkable that only the small amount described above (and a few other isolated parcels) escaped preparation for and provision to posterity.

The broad outlines of the NNEs are as follows:

- Division I — Electromagnetic Separation Project
- Division II — Gaseous Diffusion Project
- Division III — Special Separations Project
- Division IV — Plutonium Project
- Division V — Los Alamos Project
- Division VI — University of Rochester Project
- Division VII — Materials Procurement Project
- Division VIII — Manhattan Project

Biomedical research appears primarily in volumes of Division IV and VI. The health volumes of Division IV are:

- Vol. 20 — Industrial Medicine (survey and collected papers)
- Vol. 22B, C — Effects of X and Gamma Rays
- Vol. 22D — Effects of Slow and Fast Neutrons
- Vol. 22E — Effects of External Beta Radiation
- Vol. 22F, G, H — Not published
- Vol. 22I — Histopathology of Irradiation from External and Internal Sources
- Vol. 23 — Toxicology of Uranium

The work reported in these volumes was accomplished at the Metallurgical Laboratory, University of Chicago; Clinton Laboratories, Oak Ridge; Crocker Laboratory, University of California, Berkeley; Hanford Engineer Works, Richland, Washington; and National Cancer Institute, Bethesda, Maryland. The editor for these health volumes was Raymond E. Zirkle, as remarked earlier. The volumes from Division VI (Rochester) were all in the health field. Those pertinent to internal emitter research were:

Vol. 1 — Pharmacology and Toxicology of Uranium Compounds
published in two major parts, 1949 and 1953, each
requiring two volumes in terms of binding, but not
numbering.

Vol. 3 — Biological Studies with Polonium, Radium, and Plutonium

There were also volumes concerning the external radiation studies done at Rochester.

Appendix D

Abbreviations and Acronyms

ABCC	Atomic Bomb Casualty Commission
ABM	Antiballistic missile
ACGIH	American Council of Governmental Industrial Hygienists
ACRH	Argonne Cancer Research Hospital
ACS	American Chemical Society
AD	Aerodynamic diameter
AEA	Atomic Energy Authority, U.K.
AEC	Atomic Energy Commission
AECD	Atomic Energy Commission Declassified (Report)
AERE	Atomic Energy Research Establishment, U.K.
AFRRI	Armed Forces Radiobiology Research Institute
ALARA	As low as reasonably achievable
AMAD	Activity median aerodynamic diameter
ANL	Argonne National Laboratory
ANP	Aircraft nuclear propulsion
ANS	American Nuclear Society
ANSI	American National Standards Institute
AVF	Asimuthally varying field
AWRE	Atomic Weapons Research Establishment, U.K.
BAL	British anti-lewisite
BaP	Benzo[a]pyrene
BCL	Battelle-Columbus; Battelle Memorial Institute's facility in Columbus, Ohio

BEAR	Committees and their reports on Biological Effects of Atomic Radiation, under U.S. National Academy of Sciences–National Research Council (1960s)
BEIR	Several committees of the National Academy of Sciences–National Research Council on Biological Effects of Ionizing Radiation and their reports. Usually followed by a Roman numeral. (1970s and 1980s)
BFWT	Body free-water tritium
BMI	Battelle Memorial Institute
BNL	Brookhaven National Laboratory
BNW	Battelle–Northwest; Battelle, Pacific Northwest Laboratories, Richland, Washington
BRH	Bureau of Radiological Health (for many years under the U.S. Public Health Service, later the U.S. Food and Drug Administration)
BWR	Boiling water reactor
CAL	California State Water Pollution Control Board
CARL	Comparative Animal Research Laboratory (later name for UT–AEC Farm)
CBF	Controlled background facility
CEA	Commissariat à l’Energie Atomique, France
CEC	Commission of the European Communities
CERT	Controlled environmental radioiodine release tests, Idaho Falls
CF	Concentration factor
CFR	Code of Federal Regulations
CH-	Chicago report (from MED days) followed by number
CMA	California Medical Association
CMD	Count median diameter
CNEN	Comitato Nazionale per l’Energia Nucleare, Italy
CR	Cumulative rad
CSU	Colorado State University
CUEX	Cumulative exposure index
CUMEX	Cumulative hazard index
CWLM	Cumulative working level month
DAAG	Dose Assessment Advisory Group
DASA	Defense Atomic Support Agency
DBER	Division of Biological and Environmental Research, DOE, ERDA
DBM	Division of Biology and Medicine, AEC
DF	Discrimination factor

DHEW	Department of Health, Education and Welfare
DHHS	Department of Health and Human Services
DNA	Defense Nuclear Agency; deoxyribonucleic acid
DoD	Department of Defense
DOE	Department of Energy
DOH	Division of Occupational Health, AEC
DTPA	Diethylenetriaminepentaacetic acid—a chelating agent
ECF	Extracellular fluid
EDDHA	Ethylenediamine di O-hydroxyphenylacetic acid
EDTA	Ethylenediaminetetraacetic acid—a chelating agent (followed by related agents, DTPA, DETA, and DFOA and their zinc or calcium salts, see chapter 19)
EF	Equilibrium factor
EG&G	Edgerton, Gormenhausen, and Grier
EIS	Environmental impact statement
EML	Environmental Measurements Laboratory (later name for the Health and Safety Laboratory in New York)
EPA	Environmental Protection Agency
ERDA	Energy Research and Development Administration
EULAP	European Late Effects Project Group
FAO	Food and Agricultural Organization
FAP	Fused aluminosilicate particles—used at ITRI as a carrier in aerosols
FASEB	Federation of American Societies for Experimental Biology
FDA	Food and Drug Administration
FIDLER	Field instrument for detection of low-energy radiation, a portable radiation survey instrument
FP	Fission products
FPFRT	Fission product field release test
FR	<i>Federal Register</i> , USA
FRC	Federal Radiation Council, USA. Also joint reports of the Federal Radiation Council–National Academy of Sciences
GPO	Government Printing Office
HASL	Health and Safety Laboratory of AEC in New York
HEEDTA	Hydroxyethylenediaminetriacetic acid
HEHF	Hanford Environmental Health Foundation
HPS	Health Physics Society
HTGR	High temperature gas-cooled reactor

HW	Hanford Works
IAEA	International Atomic Energy Agency, Vienna
ICRP	International Commission on Radiological Protection
ICRU	International Commission on Radiation Units and Measurements
INEL	Idaho National Engineering Laboratory
IRPA	International Radiation Protection Association
ITRI	Inhalation Toxicology Research Institute (Lovelace)
IUMRRG	Interagency Uranium Mining Radiation Review Group
JCAE	Joint Committee on Atomic Energy of the U.S. Congress
LASL (LANL)	Los Alamos Scientific Laboratory (now Los Alamos National Laboratory)
LBL	Lawrence Berkeley Laboratory
LD	Lethal dose
LET	Linear energy transfer
LLL (LLNL)	Lawrence Livermore Laboratory; Lawrence Livermore National Laboratory
LMFBR	Liquid metal fast breeder reactor
LOCA	Loss of coolant accident
MDDC	Manhattan District declassified report (from World-War-II days)
MED	Manhattan Engineer District (sometimes Manhattan Engineering District). The code name for the atomic bomb project during World War II.
Met Lab	The Metallurgical Laboratory, part of the MED
MGH	Massachusetts General Hospital
MIRD	Medical Internal Radiation Dose (a committee of the Society for Nuclear Medicine)
MIT	Massachusetts Institute of Technology
MMD	Mass median diameter
MPC	Maximum permissible concentration
MPCA	Minnesota Pollution Control Agency
MPI	Microcurie present initially
MRC	Medical Research Council, U.K.
M.U.	Mache unit
Mwe	Megawatts of electrical energy
NACOR	National Advisory Committee on Radiation
NAEG	Nevada Applied Ecology Group

NAS	National Academy of Sciences
NAS-NRC	National Academy of Sciences-National Research Council
NBS	National Bureau of Standards
NCI	National Cancer Institute
NCRP	National Council on Radiation Protection and Measurements, USA
NEA	Nuclear Energy Agency
NEPA	National Environmental Policy Act
NERP	National Environmental Research Park
NERVA	Nuclear engine for rocket vehicle application
NIEHS	National Institute of Environmental Health Sciences
NIH	National Institutes of Health
NIOSH	National Institute for Occupational Safety and Health
NNES	National Nuclear Energy Series. The series of volumes published by McGraw-Hill Book Company containing significant results of the MED research in all fields.
NOAA	National Oceanic and Atmospheric Administration
NRC	National Research Council; Nuclear Regulatory Commission
NRDC	Natural Resources Defense Council
NRDL	Naval Radiological Defense Laboratory, San Francisco
NRPB	National Radiological Protection Board, U.K.
NTS	Nevada Test Site
NVO	Nevada Operations Office, DOE
NYO	New York Operations Office, DOE
NYU	New York University
OEC	Organization for Economic Cooperation and Development
OHER	Office of Health and Environmental Research, DOE
ONR	Office of Naval Research
OR	Observed ratio
ORAU	Oak Ridge Associated Universities
ORINS	Oak Ridge Institute for Nuclear Studies
ORNL	Oak Ridge National Laboratory
ORO	Oak Ridge Operations Office, DOE
OSRD	Office of Scientific Research and Development
PAG	Protective action guide
PHA	Pulse height analyzer
PHS	Public Health Service

PNL	Pacific Northwest Laboratory, operated for DOE by Battelle Memorial Institute at Richland, Washington. Sometimes also "BNW" for Battelle-Northwest.
POR-WT	Project Officer's report—weapons tests
PPR	Plutonium Project record; Plutonium Project report
PRE	Pure radium equivalent
PUREX	Plutonium and uranium recovery through extraction
PWR	Pressurized water reactor
Ra A, - B, etc.	Old terminology for members of the radium decay series. Similar designations were used for other series.
RBE	Relative biological effectiveness
REECO	Reynolds Electrical and Engineering Company
RES	Reticuloendothelial system
RNA	Ribonucleic acid
ROVER	A nuclear rocket propulsion project.
RPG	Radiation protection guide
RTG	Radioisotope thermoelectric generator
SAG	Suggested action guide
SMR	Standardized mortality ratios
SNAP	Systems for nuclear auxiliary power
SREL	Savannah River Ecology Laboratory
SRL	Savannah River Laboratory
SRP	Savannah River Plant
SWRHL	Southwest Radiological Health Laboratory
SWRL	See SWRHL
TBLN	Tracheobronchial lymph nodes
TCT	Tissue-combined tritium
TEC	Tennessee Eastman Corporation
TFWT	Tissue free-water tritium
TG-57	Test Group-57 of Operation Plumbbob, NTS
TGLD	Task Group on Lung Dynamics (ICRP), sometimes TGLM for Task Group on Lung Model
TGLM	Task Group on Lung Model (ICRP), sometimes TGLD for Task Group on Lung Dynamics
TID	Technical Information document
TLD	Thermoluminescent dosimeter
TMP	Test Manager's Advisory Panel, NTS

TTR	Tonopah Test Range
TU	Transuranium
TVA	Tennessee Valley Authority
UC	University of California (branch usually follows)
UCLA	University of California, Los Angeles
UCRL	University of California Radiation Laboratory
UNSCEAR	United Nations Scientific Committee on the Effects of Atomic Radiation
UR	University of Rochester
USAEC	See AEC
USAF	U.S. Air Force
USDA	U.S. Department of Agriculture
USDHEW	See DHEW
USDHHS	See DHHS
USDoD	See DoD
USDOE	See DOE
USEPA	See EPA
USERDA	See ERDA
USNRC	See NRC
USPHS	See PHS
USTR	U.S. Transuranium Registry
USUR	U.S. Uranium Registry
UT	University of Tennessee
UT-AEC	University of Tennessee-Atomic Energy Commission Farm, Oak Ridge
UW	University of Washington
WASH	Report from Washington Headquarters of AEC or subsequent agency
WHO	World Health Organization
WL	Working level
WLM	Working level month
WLY	Working level year

Index III Subjects

Key: f = figure; n = footnote; t = table

A

Accelerators (including cyclotrons)

and accelerator-produced isotopes,
286-92, 1517, 1521, 1715, 1755, 1760, 1774,
1776-78 (see also chapter 5)
and production of plutonium, **338-40**, 340(n)

Actinides. See also Americium; Curium; Neptunium; Plutonium; Transplutonic elements

and future research needs, **1837-38**
postwar research on, at Berkeley, **406-8**
research on at Hanford, **440-41**
research on at Los Alamos, **450-54**

Actinium, 408

in the environment, 1349(t)

Actinium series, 2, 5(t), 7, 8(f)

Aerosols (and aerosol science), 509, **553-60**, **592-93**, **610-11**, **656-57**, 657(t), 1821; 1822, 1823, 1824

from carbon arc, 514, **518-19**, 520(f)
and cascade impactors, **539-40**, 555, 555(n), 592,
610
at Chicago, **518-22**, 520(f), 521(f), 522(f)
conferences on (air cleaning), 554
dispersion of, **1262-67**, 1263(f), 1265(ff), 1266(f)
dusts and dust feeds for, 89, 539
electromicroscopy as applied to, 509, 514,
539(n), 603, 610
electrostatic precipitators for, 610, **1545-46**,
1548, 1551, 1552, 1553
from exploding wires, 518
and fused montmorillonite clay particles,
593(n), 594
and general air pollution problems, **625-26**, 634,
638
at Hanford, 583, 584(ff)
at Health and Safety Laboratory, 557, **629-30**
at Los Alamos, 557, **630-32**
at Lovelace, **590-93**, 592(f)

and microspheres, **644-47**, 646(t), 647(t)
mixed (radioactive and other), 638
monodisperse, 560, **603-6**, 605(f)
monographs and handbooks on, 537, **553-54**, 627
at Nevada Test Site, **1198-1203**
at New York University, 557
from nuclear rockets and related devices, 568,
653-55
at Operation Roller Coaster, **1203-7**
particle size and toxicity of, **540-42**, 541(f), 549,
649 (see also Hot particles)
polydisperse, 560
production methodologies for, in World War II,
510-14, **518-22**, 520(f), 521(f), 522(f)
at Rochester, **555-56**, **612-15**, 614(f), 615(f)
radioactive, special considerations for, **559-60**
in uranium mines, **135-45**

Aerosol sections at inhalation centers, **553-60**

Agents adjunctive to radioisotopes, **1819-21**. See also Inhalation studies; names of individual elements; Uranium miners

Aircraft Nuclear Propulsion Project. See Safety tests for fission products

Air monitoring

after Manhattan Engineer District, **1551-55**,
1551(f), 1555(f)
in Manhattan Engineer District, **1544-48**,
1545(ff), 1546(f), 1547(ff)

Air sampling, methods and devices for, 1545(ff), 1547(ff), **1544-48**, **1551-55**, 1551(f), 1555(f) cascade impactors, **1552-53** gas sampling, continuous, 1547, 1547(f), 1551, 1552 impingers, **1544-45**, 1552 Lucas cell, **1556-57** for plutonium, 1551, 1552, 1552(n), 1554, 1555 for radon and thoron, 146, 1544, 1545, 1554, **1555-58**

Kusnetz method, 1557
for tritium, 1554, 1555
working level meters, 1557, 1558

- Alamogordo cattle, 885, **1069-70**, 1070(t), 1071(f)
- Alaskan Operations, **1232-33**, **1239-40**
- Alginate, 1635, **1636-37**, 1651, 1669
- Alpha Laboratory (Rochester), **612-15**, 614(ff), 615(f)
- Alpha particles. *See names of individual elements*
- Aluminum, in nuclear medicine, 1777(t)
- Amber and plastic, for insulating instruments, 1515
- Amchitka, 1239, 1240
- Americium, 8, 463, 1135, 1137, 1138, 1138(f), 1452, 1454(t), 1473. *See also* Transplutonic elements
- autoradiography of, 369
- and bone, 342(f), **369-71**, 370(t)
- and bone tumors, 479
- distribution and excretion (metabolism) of, **369-71**, 370(t), 406, 407, 462, **470-81**, 474(f), 475(f), 477(f), 478(t)
- environmental transport of, 1308(t)
- excretion of, 477(f)

Environment, studies of (*continued*)

- at Nevada Test Site, **932-73**, **1195-1203** (see also Nuclear weapons tests; Fallout)
- by Nuclear Energy Agency, 841, 842(f)
- at Oak Ridge, **768-73**, 771(f), 777(t), **805-9**, 805(f), 806(f), 808(f), 820
- and Operation Crossroads, **888-91**
- and Operation Roller Coaster, **1203-7**
- in Pacific Ocean, **782-83**, 892, 895, 896, **916-28**
- near Columbia River estuary, 768, **800-801**
- plankton, 758, 765, 773, 815, **818-19**, 834, 835, **837-38**
- and Project Plowshare, **1221-33**
- at Puerto Rico Nuclear Center, 781, 838
- near reactors, **757-68**, 764(f), 767(t), 767(n), **774-77**, 780, 781, 784, **786-90**, **811-13**, 813(f), 816, **824-32**
- in Richland and Ringold Farms, Washington, 803, 804
- at Rocky Flats Plant, **813-16**
- salmon and trout, **757-59**, 759(n), **763-64**, 819, 821, 822, 839
- at Savannah River Site, **774-77**, 775(f), 776(f), 777(t), 780, 816
- by Scripps Oceanographic Institution, **782-83**
- and Stafford Warren, 757, 762(n), 783
- in Sweden, 784, **833-34**, 856, 857
- Symposia and compendia on, 766, 767, 768, 771, 778(n), 784, **790-93**, 814, 832, 833, 834, **836-37**, 839, **844-57**
- at Tonopah (see Environment, studies of, and Operation Roller Coaster)
- transport of radionuclides in environment, **1260-1368**
- transuranics, 814, **832-35**
- at Trinity Site, **884-87**, **928-32**, **1019**
- and tritium, 776(f), **835-41**
- in United Kingdom, **786-90**, 788(f), 825, 834, 841(n)
- by University of Georgia (at Savannah River Plant), 774, 776
- by University of Washington, **757-58**, 762, 765, 770(n), 801, 817, 819, (see also Fisheries radiobiology; *Index II*)
- near uranium mills and refineries, **778-80**, **808-9**, 810
- by U.S. Public Health Service, 778, 781, 782, 837
- in USSR, 784, 790, **820-21**, **1843-48**
- at West Valley, New York, 780
- by Woods Hole Oceanographic Institution, 781

Epidemiology

- future research needs in, **1832-33**
- of miners exposed to radon and daughters, **122-30**, 147, 159, 165
- of plutonium workers, **1463-69**
- of uranium workers, **122-30**, **133-35**, **147-59**, 159(f), **1479-81**, 1481(t)

Europium, 638, 639

Excretion of radionuclides. *See also names of individual elements*

- influence of therapy on, **1588-91**, **1593-94**, 1594(t), 1601(f), **1602-6**, 1621, 1622(f), 1623(f),

- 1624, **1626-28**, 1636, 1642, 1643(f), 1646(t), **1648-51**, 1655, **1657-60**, 1658(f), 1661-64(t), 1666, 1668

F

Facilities. *See also Index II*

- at Berkeley, 313(f), **408-9**
- at Hanford, 563(f), 566(f), 568(f), **575-76**
- at Los Alamos, 450(f), 451(f)
- at Lovelace, **606-8**, 606(f), 607(f)
- at Rochester, **612-15**, 614(f), 615(f), 617(f)

Fallout, **879-1040**

- at Ann Arbor, 938
- in Arctic, 978, 1001
- and beta activity in marine organisms, 918(f)
- and beta burns, 885, 895, 897, 901, 902(f), 914, 922, 1070
- at Bikini, 905(t)
- from Bravo test, **897-919**, 899(f), 900(f), 915(f), 916(f)
- from Chernobyl, **1843-44**
- at Chicago, 937
- contamination of food by, 891, 894, 905, 905(n), 906(f), 909, 910, 911, 913, 913(f), **918-19**, 920, 921(t), 923, **925-27**, 935, 940, 949, 950, 951(t), **952-55**, 982, 984(f), 986, 986(f), 987, 989, 990, **993-1003**, 994(t), 995(t), 997(f), 998(f), 999(f), 1000(t), 1007, 1011(t), 1025, 1027, 1845
- doses from, in Utah, 964(t), 965(t)
- and fertility in animals, 1070, 1070(t), 1071(f)
- and film, **885-86**, 886(f)
- hidden doses from, **1015-16**
- infant mortality from, **1016-25**
- and leukemia, 909, **956-60**, 958(f), 959(f), **965-66**, 968(n), 971, 972, 985, 987, 1006, 1015, 1021
- and Marshallese, **899-911**, 902(f), 903(f), 904(f), 905(t)
- and meteorology, 937, 939, 941, 992, 1025
- methods for measurement of, 937, 938(f), 939, **980-81**, 980(f), 998(f), 999(f)
- nationwide and worldwide, **973-1004**, 979(f), 980(f), 981(f), 983(t), 984(f), 985(f), 986(f), 988(f), 994-95(t), 995(t), 997(f), 998(f), 999(f), 1000(t)
- and Nevada Test Site, 944(t), 945(t)
- offsite exposures to
 - from Nevada Test Site, **936-47**, **947-70**, 948(f), 951(f), 952(f), 958(f), 959(f), 963(f), 964(t), 965(f)
 - in Pacific, **911-19**, 918(f)
- onsite exposures to
 - at Nevada Test Site, **934-47**, 944(t), 945(t), **970-73**
 - in Pacific, **894-96**, 894(n), **897-911**, 899(f), 900(f), 904(t), 905(t), 906(t), 907(t), 908(t), **919-28**, 921(t), 924(f)
- at Rochester, 886(f), 937
- at Salt Lake City, 937, 950
- and soil, 920, 921(t), 924(f), 925, 928, 930, 931, 931(t), 940, 944(t), 956(n), 964, 981, 981(f), 987
- standards for, **1004-12**
- and Sunshine Project, **975-77**, 978(n), 979(f), 982

Fallout, (*continued*)

- and thyroid, **904-9**, 904(t), 907(t), 908(t), 923, 942, 949, 950, 951(t), **952-57**, 952(t), **967-68**, **988-90**, 1002, 1010, 1012
- trajectories for, from Nevada Test Site, 948(f)
- at Troy, 937, 938, 1021
- in Utah, **949-68**
- and leukemia, **956-60**, 958(f), 959(f), 968
- and thyroid, **949-56**, 951(t), 952(t), **956-57**, **966-68**
- Federal Radiation Council, **1399-1403**, **1427-28**
See also *Index II*
- Ferri-ferrocyanide (Prussian blue), 1637, 1651 and therapy, 1637
- Fetal and juvenile mammals, research on, at Hanford, **443-46**
- Film badge, 1528, 1543, 1558
- Fish. See also *Environment*, studies of; *Salmon* and *trout*
 - contamination of, **757-60**, **762-67**, 767(t), 772, 785, 785(f), 790, 800, 802, 807, 812, 815, 821
 - radiosensitivity of, 819, **821-22**, 824, 839, **1124-27**, 1125-26(t), 1127(t)
- Fisheries radiobiology
 - in Clinch and Tennessee Rivers, **771-72**, **805-7**
 - at Hanford and Columbia River, **757-68**, 758(f), 764(f), 766(f), 767(n,t), 770(n), **798-802**, 800(f)
 - at Pacific Proving Grounds, 925
 - at Savannah River Site, 774, 782
 - by University of Washington, **757-58**, 762, 765, 770(n), 801, 817, 819, 888, 891, **892-96**, **917-18**, 918(f), 925, **928-29**, **1232-33**, **1239-40**, 1806, 1806(f) (see also *Environment*, studies of, in *Columbia River*)
- Fission Product Field Release Tests (Idaho Falls), **1216-21**, 1218(f)
- Fission products, **299-326**. See also *Fallout*; *Inhalation studies*, with fission products; *King-sized experiments*; *names of individual elements*; *Reactors*
 - autoradiography of, 304, 308, 309(f), 310(f)
 - biomedical research on at Argonne National Laboratory, 322, **387-99**
 - at Berkeley, **302-12**, **399-400**, **400-406**, 403(f), 404(f), 408, **1081-83**, **1083-84**
 - at Brookhaven, 810, **1084-85**
 - at Clinton Laboratories, 314, 315
 - at Cornell University, 465, **1074-76**, **1104-8**, 1108(f)
 - at Davis, **430-32**, 431(t), 1076
 - at Hanford, 324, **757-68**, 764(f), 766(f), 767(t), 777(t), **798-804**, 799(f), **1085-88**, 1086(f)
 - at Health and Safety Laboratory, 466, **810-11**, 943, **1019-20**
 - at Lawrence Livermore, 811, **1089-90**, **1289-90**
 - at Los Alamos, **450-52**, **454-61**, 455(f), 456(f), 458(t), 459(f), **810-11**, 1088
 - at Lovelace, **432-33**, **588-603**, 596(t), 597(ff), 598(t), 599(t), 600(t), 606(f), 607(f)
 - at Metallurgical Laboratory, **312-22**
 - at Naval Radiological Defense Laboratory, **1064-69**

- at New York University, **811-13**, 813(f)
 - at Oak Ridge, **768-73**, 771(f), 773(t), 777(t), **805-9**, 805(f), 806(f)
 - at ORINS: **463-64**
 - at Savannah River Plant, **774-77**, 775(f), 776(f), 777(t), 816
 - at Southwestern Radiological Health Laboratory, 998, 998(f), 999(f), **1077-80**, 1077(f), 1078(f), 1079(f)
 - at UCLA, 466, **939-47**
 - in United Kingdom, **324-25**
 - at University of Rochester, 323, **464-65**, 1089
 - at University of Utah, **409-29**, **949-52**, 951(t)
 - at UT-AEC Farm, 463, **1069-74**, 1070(t), 1071(f), 1072(f), 1087, **1090-94**, **1104-6**
 - in USSR, 470
 - and bone, 305, 305(t), 306, 306(f), 307, 308, 309(f), 310(f), 311, 311(f), 316, 317(f), 318, 320, 321, 325
 - in bone marrow, 306, **315-16**, 321
 - carcinogenic effects of, **317-19**, **390-97**, 390(f), 391(f), 395(f), **417-24**, 419(f), 420(f), 422(t), 423(f), 464, **595-603**, 598(t), 599(t), **631-32**
 - and chemistry and radiocolloids, **321-22**
 - from cyclotrons (accelerators), at Berkeley, **302-4**, 312, 313(f)
 - excretion of, 316, 317, 320, 321, 325
 - and fibrosis, 562, 595, 598(t), **599-601**, **601-11**
 - field releases (experimental) of, **323-24**, **1216-21**, 1218(f)
 - and goldfish, **319-20**, 1121(n)
 - hematological effects of, 316, 321
 - pathology from, 318, 321
 - and plants, effects on, **1143-46**
 - plant uptake of, 311, **1127-37**, 1129(t), 1130(t), 1131(t), 1136(t), **1139-43**, 1140(t), 1143(f)
 - production of, **300-302**, 301(f)
 - radiations from, 302, 308(n)
 - radiochemical procedures for, 308(n), **314-16**, 315(n)
 - and related elements, postwar research on, at Berkeley, **399-400**, **400-406**, 403(f), 404(f)
 - research on, at Los Alamos, **456-61**
 - retention of (see *Fallout*; *King-sized experiments*; *names of individual elements*)
 - in soft tissues, 305(t), 306, 307, 307(f), 316, 317, 317(f), 318, 320
 - standards for exposure to, **1004-12**, 1342, 1428, 1429, **1432-33**, 1434(f), **1490-91**
 - therapeutic removal of, 1589, 1590, **1620-25**, 1622(f), **1647-51**, **1659-60** (see also *Strontium*)
 - transfer of, from mother to offspring, 319
 - uptake and distribution of, effect of diet on, 311, 311(f), 324
 - validation of standards for, **1482-85**
- Future research needs
- actinides, **1837-38**
 - comparative effectiveness of radioisotopes and external radiation, **1743-46**, 1746(f), 1833
 - dosimetry, cellular level, **1808-9**
 - environmental studies, **1839-1940**

Future research needs (*continued*)

epidemiology, **1832-33**
 external versus internal radiation sources, 1833
 fission products, **1837-38**
 inhaled dusts and particles, **1838-39**
 inhaled gases, 1839
 instrumentation, 1841
 nuclear medicine and tracer chemistry, 1842
 plutonium, **1837-38**
 polonium and thorium, **1836-37**
 radium, **1834-35**
 radon in dwellings, 1836
 radon and uranium, 1836
 salmon and trout, **1831-32**
 species comparison, 1800, **1831-32**
 standard setting, **1840-41**
 therapeutic removal of radionuclides, **1841-42**
 thorium, **1836-37**
 uranium, **1835-36**

Radioecology, marine (*continued*)

- at New York University and Lawrence Livermore, 838
 - at Oak Ridge, **771-72**, **805-7**, 805(f), 806(f)
 - at Oregon State, 801, 1090
 - at Savannah River, **774-77**, 816
 - at Sequim, 800(f)
 - in United Kingdom, 786
 - at University of Washington, 801 (see also Fisheries radiobiology: Pacific Proving Grounds)
 - in West Germany, 790
 - at Nevada Test Site, **942-47**, 944(t)
 - at Oak Ridge, **768-73**, 771(f), 773(t), 777(t), 780(n), **805**, **807-9**
 - at Pacific Proving Grounds, **919-28**
 - at Palomares, **1207-10**
 - at Savannah River, **774-77**, 775(f), 776(f), 777(t), 780
 - at Scripps Oceanographic Institution, **782-83**
 - of selected radionuclides, 794, 795-98(t), 818(t)
 - terrestrial, 845, **846-47**, **851-52**, **855-56**, **1127-47**, 1129(t), 1130(t), 1131(t), 1136(t), 1138(f), 1140(t), 1143(f), 1145(t), 1146(f)
 - at Thule, **1207-10**
 - at Trinity Site, 887, **928-32**, 931(t)
 - at Woods Hole Oceanographic Institution, 752, 794, 832, 833, 834, 1090
- Radioimmunoassay, **1717-18**, 1774
- Radiolead, in nuclear medicine, 1735
- Radiopharmaceuticals, 1717, **1726-27**, 1734, 1775, 1780
- Radium, 1, 2, 3(t), 4(t), 6(f), 7(f), 8(f), 9(f), 10(f), 11, 12, 1461
- autoradiography of, **348-49**, 348(f)
 - biomedical research on
 - at Argonne Cancer Research Hospital, 54
 - at Argonne National Laboratory, **52-61**
 - at Center for Human Radiobiology, **59-61**
 - in Manhattan Engineer District, **32-41**
 - at Massachusetts General Hospital, **41-42**
 - at Massachusetts Institute of Technology, **27-30**, **41-42**, **44-50**, 48(f), 51(ff)
 - at Metallurgical Laboratory, **32-37**
 - at National Cancer Institute, **42-43**
 - in the early twentieth century, **22-26**
 - in the 1930s, **26-32**
 - during World War II, **32-43**
 - post-World War II, **43-71**
 - at Berkeley, 33
 - at Davis, 62
 - at University of Rochester, **37-41**, **64-65**
 - at University of Utah, **61-62**
 - and bone
 - deposition and metabolism in, **27-34**, 42, 44, **52-53**, 54(f), 63, 68
 - effects, **23-27**, 36, 39, **49-50**, 51(ff), **55-61**, 57(f), 58(f), 62, 63, 67(t), 68, 68(t), **69-71**
 - microdistribution ("hot spots"), 63
 - and cancer
 - in bone, 25, 36, 39, 42, **49-50**, 51(ff), 57, 57(f), 58(f), 60, 61, 65, 66, 67(t), 68(t), 69
 - in other tissues, 50, 60, 61, 67(t), 68(t), 69
 - and chemists, 25, 44, 45, 49, 53
 - classical x-ray score for, 49, 50, 51(f)
 - in animals and humans (comparison), 38, 42, 52, 53
 - and dial painters (luminizers), 21, **23-26**, **28-29**, 31(f), 32, 41, **42-63**, 48(f), 51(ff), 54(f), 55(f), 56(f), 57(f), 58(f), **71-72**, 710, 719
 - discovery of, **21-23**
 - distribution and retention of, **30-32**, **33-40**, 35(ff), 41, 42, **52-53**, 54(f), 63
 - and dose-response relationships
 - in animals, 61
 - in humans, 50, 51(ff), 57, 57(f), **58-60**, 58(f)
 - in drinking water, **65-66**, **778-79**, 1337, **1339-41**
 - and dose protraction, 69
 - effects of (see also Bone; Cancer)
 - in blood, 36, 39
 - chemical, 39
 - roentgenographic changes, **49-51**, 51(f), 58, 62
 - eye changes, 36, 62
 - hematopoietic changes, 37, 40, 40(t), 67(t), 68(t)
 - in organ systems, **36-42**, 60, **69-70**, 67(t), 68(t)
 - in environment, 796(t), 1126(t), 1337, **1339-41**, 1409
 - and epidemiology, **45-46**, **54-60**, **62-63**
 - and Eben Byers, **26-27**
 - excretion of
 - in animals, **30-31**, 33, 38, 39, 41
 - in humans, 27, 29, **30-31**, 38
 - and future research needs, **1834-35**
 - histopathology from, 361(t)
 - and jaw necrosis, 24
 - and kidney, 1589
 - in-vivo counting of, **27-29**, 53
 - in food, 63, 64, 65
 - in natural waters, **63-66**, 147
 - in nuclear medicine, 1712, 1775, 1776
 - isotopes of, used as tracers, **284-85**
 - measurement of, **27-29**, 1516, 1519, 1544
 - mesothorium, **46-48**, 48(f), 49
 - meter-arc calibration technique for, 27
 - and patients, **24-26**, 25(n), **27-30**, 31(f), 32, 45, 47(n), 48(f), 51(ff), **52-54**, **56-58**, 57(f), 58(f), **66-71** (see also Radium, dial painters)
 - Peteosthor, **66-67**
 - and Pure Radium Equivalent, **48-49**
 - Radithor, 26, 26(n)
 - standards for, 71, 1409, **1412-18**, 1427, 1429, **1432-33**, 1441, 1441(t), 1453
 - validation of, 1458, 1484, 1485
 - therapeutic removal of, **29-30**, **1588-89**
 - toxicity of, **361-67**, 362(t), 363(t), 364(ff), 365(f, t), acute, **34-41**
 - transport of, environmental, 1269(t), 1270(t)
 - and U.S. Navy, 32, **43-45**
 - x-ray score for, 49 (see also Radium, classical x-ray score for)

Radium series, 121(f)

- in environment, 796(t)

Radium-223, postwar research on, at Berkeley, 408

inhalation studies with

acute, **90-91**, 92(f), 98, 102, **536-49**, 1421(f)

long-term, **96-98**, **536-49**

and kidney damage, **93-94**, **95-96**, **98-100**

measurement of, **88-89**, 89(n)

monitoring of, 1554

pathology of uranium poisoning, **95-96**

standards for, 104, 1349(t), 1401, **1418-22**, 1421(f), 1441, 1441(t), 1442, **1473-82**, 1477(t), 1478(t), 1481(t)

derivation of, **1418-22**, 1421(f)

validation of, **1473-82**, 1477(t), 1478(t), 1481(t)

therapeutic removal of, 1589, 1599, 1604, 1606, 1624, 1646, 1653, 1677

tissue distribution of, 91, 96

transport of, environmental, 1269(t), 1276(t), **1304-9**, 1308(t), 1335(t)

toxicity of, **88-102**

chemical, **89-96**, **98-99**, **1418-22**, **1473-81**

relative (of various compounds), 92(f)

Uranium fuel cycle and the environment, **1351-53**.

See also Reactors, liquid metal fast breeder

Uranium mills and millers, 131, 135. See also Radon and radon daughters

Uranium mill tailings, 175, 179

Uranium miners, **122-61**

bioassay of, 174

cancer in, **123-30**, 127(t), 129(t)

early effects in, **122-25**

epidemiologic studies of, **147-59**, 154(n), 159(f)

medical surveys of, **122-30**, **143-59**

and radon and daughters, **128-30**, 129(t), **136-45**

Uranium mines

- in Belgian Congo, 133(n), 134, 134(n), 135
- in Canada, 133, 134, 135, 145, 157
- control of, **173-74**
- in Czechoslovakia, 122, 123, 126, 127, 134, 135, 154, **156-57**, 156(n), 159(f)
- early history of, **122-25**
- in Germany, **122-29**, 129(t), 154
- role of government
 - in Europe, **126-27**
 - in United States
 - Atomic Energy Commission, 137, 143, 147, 149, **150-51**, **155-56**
 - Federal Radiation Council, **140**, 151, 152, 156
 - Health and Safety Laboratory (HASL) of AEC, 137, 147, 173, 174, 175
 - Inter-Agency Review Group, 152, 156
 - National Academy of Sciences-National Research Council, 140, 152
 - New York Operations Office of AEC, 149
 - Public Health Service, 142, 143, 145, **147-55**, 175
 - Schneeberg and Joachimsthal (Jachymov), **122-29**, 127(t), 129(t), 132, 134(n), 160 and related mines, **124-25**
 - states, American, 149, 150
 - surveys of, 129(t), 142, 148, 148(n), **149-51**
 - in United States (Colorado Plateau), 133, 134, 134(n), 142, **147-56**
 - ventilation of, 141, 143, 155, 173
- Uranium Registry. See U.S. Uranium Registry
- Uranium series, 2, 3(t), 6, 6(f), 7(f), 9(f), 236(t)
- Uranium-232 or -233, 98, **102-4**
 - effective toxicity of, 481
- Uranium workers, **98-100**
 - autopsy program for (see Epidemiology; Uranium, epidemiologic studies)
 - epidemiologic studies on, 99, 99(n), **1480-81**, 1481(t)
- U.S. Advisory Committee on X-Ray and Radium Protection, 1395, 1413
- U.S. Atomic Energy Commission and standards, 1408, 1425, 1461, 1469, 1473. See also *Index II*
- U.S. Congress and standards, 1407, **1410-11**, 1417
- U.S. Department of Energy, Transuranium Element Research Program, 828, 829(f)
- U.S. Environmental Protection Agency and standards, 1404(n), **1409-10**. See also *Index II*
- U.S. National Bureau of Standards, **1395-96**, **1413-14**, 1413(n). See also *Index II*
- U.S. Nuclear Regulatory Commission and standards, 1408. See also *Index II*
- U.S. Public Health Service, Bureau of Radiological Health and Standards, **1403-4**. See also *Index II*

U.S. Transuranium Registry, **1469-71**U.S. Uranium Registry, **1478-79**

V

- Victoreen "R" meter, 1543
- Vitamins, in therapy, **29-30**, 1588, 1633, 1649

W

- Water. See Drinking water; Ground water transport; Surface water transport
- Windscale, **786-90**, 788(f), 825, 1280, 1286, 1327. See also *Index II*
- Whole-body counting. See Counters and counting
- Working-level meter and methods, 1557, 1558
- Wound decontamination, 1607(n), 1612, **1613-14**, 1621, 1633, 1634, 1638, 1653, 1654, 1655, 1657, 1658(f), 1659, 1660, 1661-64(t), 1668, 1669, 1670, 1675

X

- Xenon, 304, 305(t), 306, 307, 308, 312
 - in environment, 796(t)
 - reactivity of, 689
 - research on, during World War II, **685-86**
 - sources of, 689
 - toxicity of, **685-86**
 - transport of, environmental, 1317(f)

Y

- Yttrium, 304, 305(t), 306(f), 307(f), 308, 311, 317, 318, 320, 324, 1087, 1119, 1125(t), 1127(t), 1128, 1129(t), 1130(t), 1134, 1136(t), 1137, 1148
 - effects of, 393
 - in environment, 797(t)
 - distribution and excretion (metabolism) of, 397, 345(f)
 - in nuclear medicine, 1763
 - therapeutic removal of, **1579-80**, **1589-90**, 1601, 1621, 1641(t), 1642, **1649-50**

Z

- Z-A plot, 2, 6(f), 10(f)
- Zirconium, 304, 305(t), 306(f), 307(f), 308, 310(f), 311, 320, 1129(t), 1136(t)
 - in therapy, **1593-94**, 1594(t), **1600-1604**, 1601(f)
 - toxicity of, **1655-57**
 - transport of, environmental, 1317(f)
- Zymosan. See Therapy (removal of radionuclides)
